a pinion of six teeth on the axle of the contrate wheel *i*, which has forty-eight teeth cut parallel to its axle by which it turns a pinion of six leaves fixed to the balance wheel *k*. The pivots of the axle of this wheel turn one in a frame *F*, called the potance, fixed to the upper plate, and the other in a small piece called the counter potance, so that when the two plates are put together the balance wheel pinion may work in the teeth of the contrate wheel. The balance wheel has fifteen teeth by which it impels the balance *l*, the axle of which, called the verge, has two pallets projecting from it nearly at right angles to each other; these are acted upon by the balance wheel, as shown enlarged in fig. 4, where the lower pallet is supposed to be in contact with one of the teeth of the balance wheel, which as it turns pushes the pallet round and the balance with it, till the balance has made about a quarter of a turn, the tooth of the balance then slips off and escapes. In this position the watch would run down if it were not for the upper pallet at that instant engaging another tooth on the opposite side of the balance wheel, which, as it moves in a contrary direction, pushes the balance back again till the tooth escapes the pallet, the lower pallet then engages the wheel as before, and thus the action is continued; *m* is the pendulous spring which is made of steel and of a spiral figure; the inner end of it is fixed to the verge just beneath the balance, and the outer end pinned to a stud fixed to the top of the upper plate of the watch, so that the balance will rest only in one position, and if it is moved either way by the balance wheel the spring will have a tendency to bring it to the same position again. When the lower pallet, for instance, has just liberated a tooth of the balance wheel, the pendulous spring is strained and returns the balance to its point of rest instantly, the balance wheel following the upper pallet by the action of the main spring; the balance will, of course, by the momentum which it has received, vibrate past its natural point of rest, but this is, by the assistance or force of the main spring upon the pallet, made to vibrate sufficiently in the other direction to permit the tooth to pass.

It is evident that, by lengthening or shortening this spring, the velocity of the balance will be regulated; this is done by a contrivance shown in fig. 5, consisting of a plate of brass screwed to the top of the upper plate; at one place it is hollowed out to receive a wheel *n* of twenty teeth, which turns a segment of a wheel *p* called the curb; this moves round in a circular groove, which has a projecting leaf *q* with a notch in it to receive the pendulous spring, so that by turning the wheel with a key put on the square part of the axle, the spring is lengthened or shortened so as to give a different power and make the balance vibrate quicker or slower: the axle of the wheel has a hand upon it which works round upon a graduated dial, so that when the rate is altered it may serve as a guide to set it by. The upper pivot of the verge runs in a cock screwed to the upper plate, which covers the balance and protects it from violence, and the lower pivot works in the bottom of the potance; the socket of the pivot of the balance is made in a small piece of brass which slides in a groove made in the potance, so that by drawing the slide in or out the teeth of the balance wheel shall just clear one pallet before it engages another.

The watch is so adjusted by the spring that the balance shall vibrate so as to turn the centre wheel round once in an hour, the spindle of which projects

Mechanical Processes.

Fig. 4.

Fig. 5.

Manufac-
tures.

through the lower plate, fig. 1, and has a tube fitted on it which is square at the top and carries the minute hand the other end of the tube has a pinion of twelve teeth on it which turns the minute wheel *s* of forty-eight teeth, and its pinion of sixteen, and this moves the hour wheel *t* of forty-eight teeth; the spindle of this is a tube which is put over the tube of the minute hand, and has the hour hand fixed upon it, and thus the time is indicated upon the dial plate to the degree of minutes, which is sufficiently near for common purposes. If the watch be required to show seconds, it is only necessary to continue the axle of the wheel to the dial plate and to affix a hand to it.

Balances of Watches.

Discovery
of the
isochronal
property of
the spring

(905.) The balance, by the aid of a spiral spring, performs the office of a regulator to watches, on the same principle as the pendulum does to the clock, that is, it performs oscillations in the same time when undisturbed by foreign forces, whether they be wide or narrow. For the discovery of the isochronal properties of the spring, we are, as already stated, indebted to Dr. Hooke; for although the honour of this invention is disputed with him by Huygens, there appears to be most unquestionable evidence of Dr. Hooke's priority by fifteen years. He found that the force necessary for retaining a spring in any constrained position was proportioned to its tension or deflection from its natural form. This fact, which the doctor immediately conceived might have important practical applications, he expressed and published in the form of an enigma, which was the practice of the times; the letters of which were *ce u i n o s s t*, *t, i z*, which was explained some years after by *Ut tensio sic vis*. But this property of the spring, although its application has been so important, does not seem to be strictly borne out by theory, as in the case of the accelerating action of gravity on the pendulum. Dr. Robison was of this opinion. He remarks, "that the proof of this principle rests entirely on the nicety and propriety of experiments, and long experience has shown that it is true only within certain limits." The approximation, however, is a very close one, and the application itself one of the highest importance; but in its simple state other irregularities besides those which belong to the natural elasticity of the spring occur, which require compensation similar to those of clocks; the effect of temperature are no less sensibly felt here than in the larger machine, and much ingenuity has been exercised in correcting these defects by the invention of what are termed compensation balances, which we shall now proceed to describe.

Compensation Balances.

Compensa-
tion ba-
lances.

(906.) As the velocity of the vibrations of a balance depends both upon the strength of the pendulous spring and the distance of the centre of oscillation from the point of suspension, the changes of temperature will have great influence on the rate of a watch, not merely by the expansion of the balance, which, of course, increases the radius of the centre of oscillation, but also by weakening the power of the pendulous spring, both of which effects tend to make a watch lose by an increase of temperature. We may even add to these the expansion and consequent decrease of power of the main spring, or motive power, the influence of which tends in the same manner

to make the watch lose. In the common watch these effects are, in some measure, compensated by the variable fluidity of the oil applied to the pivot holes of the balance arbor and of the other arbors of a watch, which are affected by a change of temperature in an opposite manner to that of the springs and balance; that is, an increase of temperature, by rendering the oil more fluid, gives more freedom to the action of the maintaining power and balance, and thus counteracts, in some measure, the expansion and lengthening of the springs.

Mechanical
Processes.

This natural compensation, which is very useful in the common watch, as it enables it to approach much nearer than it would otherwise do to correct time, is very inconvenient to the chronometer maker, as it interferes with the effects produced by the latter compensations, by the uncertainty and irregularity of its action, which, of course, will not admit of that degree of measurement and adjustment which the compensation by the expansion of metals will afford.

As the change of rate in a chronometer is much more than is due to the simple expansion of the balance, the correction which could be afforded by the counter expansion of another metal in the same manner as in the pendulum, would not be sufficient to effect the purpose, and the more powerful means of the change of figure of two laminæ of different metals placed together is had recourse to. In these ways the effect of heat is rendered very sensible, so much so that two thin laminæ of brass and steel placed together will curl up instantly by the heat of the hand, and as suddenly resume their original figure. It does not, however, require the aid of experiments to perceive that the effect of heat will be readily shown in this manner, when we consider that if the outer metal is expanded 3.1416 times the thickness of the inner one, the figure, if originally straight, will assume a semicircle, a degree of expansion which will be attained very readily by a small change of temperature, by having the laminæ thin and long.

Having thus attained a ready means of affording compensation, the best manner of its application becomes an important consideration. It is done in three different ways, *viz.*, first, by causing it to act exclusively on the balance itself; secondly, partly on the spring and partly on the balance; and, thirdly, exclusively on the balance itself. This latter method, although not the most modern, is the one now commonly employed, and to which we shall chiefly direct our attention.

There is every reason to believe that Harrison was the first who employed a compensation to a time-piece; but the first pocket watch made in Europe with a compensation was by F. Berthoud. It was begun in 1763, finished the beginning of 1764, and was sold in London to Mr. Pinchbeck for his Britannic Majesty King George III. The compensation acted on the spring, and was effected by laminæ of brass and steel pinned together, one end of which being fixed to the potance plate outside, the other acted on a short arm projecting from a movable arbor, a longer arm having the curb pins in it which were made to move nearly in the circle of the outer coil of the spiral spring.

Mudge, some time before the year 1770, made a watch for Mr. Smeaton, in which the compensation was also of the first class, and was effected by two long strips of brass and steel soldered together; the united piece was coiled or turned up into a spiral sufficiently close together in the coils to be free. The inner end was

Harrison's
compensa-
tion.

Berthoud's
compensa-
tion.

Mudge's
compensa-
tion.

Manu-
facture.

fixed to a circular, curbed tooth wheel, a short portion of the outer end had a sort of pivot formed on it bent in the circle of the outer coil, and supported by a small stud fixed in the curb wheel, having freedom to move easily in a hole in this stud. At this end were the curb pins, between which the pendulous spring played.

Berthould, Arnold, and others had recourse to different modes of compensation before they arrived at that one which gave them complete satisfaction. The former in his first machines used small wires of brass and steel, combined nearly like the gridiron pendulum; to those of a later date was applied a straight piece composed of laminæ of brass and steel pinned together, acting on the arm of a short lever, and on the end of the other arm, which was of some length, the curb pins were fixed. Even with those balances, which were composed of brass and steel pinned together, he adopted, as a supplementary aid, the straight compensation piece with the movable arm and curb pins.

Arnold's
compensa-
tion.

In Arnold's balances two pair of laminæ were placed parallel to the diametrical arms: on the middle of each of the combined laminæ was fixed a small wire which came through the rim of the balance, outside of which, and on the end of the wires, a small ball was fixed to each, which were pushed out or drawn in by changes of temperature.

Pl. lxiii.
Fig. 8.

Plate lxiii. fig. 8, is a representation of the compensation balance of Arnold; *ab* is a steel rim on which three pieces of metal are situated so as to slide, in order to adjust, in some degree, the equilibrium of the balance; *cc* are pieces of gold which turn spring tight on the tipped parts formed from the ends of the steel laminæ; *ee* are small screws put in through the compound laminæ which serve to adjust for small differences in the same way as the mean time screws *dd* do for greater portions of time.

Earnshaw's
compensa-
tion.
Fig. 9.

In fig. 9 is represented the compensation balance employed by Earnshaw: *dd* are pieces having a groove turned in them by which they engage the compound rim of the balance, and can be made to slide backward and forward on it; *cc* are the screws which fix them to the rim after the adjustment for heat and cold is completed; *aa* are the screws which adjust to mean time.

The chronometer when completed is put in an oven, and if it is found to lose in its rate, it shows that the compensation is not sufficient, and the adjusting pieces *dd* must be moved along the bar of laminæ towards the point of attachment; if, on the contrary, it is found to gain in its rate, it shows that it is over-compensated, and the adjusting pieces must be moved in the contrary direction, in each case taking care that the two pieces are moved in an equal degree, in order that the balance may be preserved.

These balances are now very commonly constructed with screws in the rim, by which the adjustment is effected instead of by the movable piece *d*. When upon trial it is found that the watch is not sufficiently compensated, one of the screws must be removed to a hole further; the point of attachment of the rim and of the compensation is then found to be a little in excess, and it may be remedied by unscrewing it so as to remove it further from the rim, or by changing its position with a screw of less weight. This construction will be understood from fig. 10, which is taken from the balance of a chronometer constructed by Parkinson and Frodsham.

Fig. 10.

Many other modes of compensation have been invented and are employed which are equally efficient in

VOL. VIII.

their action; but as they are all founded on the same principle, we do not conceive it necessary to enter any further on this subject, and shall, therefore, employ what our limits will permit to explain as fully as possible the many beautiful inventions for the escapements of watches which have ultimately brought this instrument to so high a degree of perfection.

Mechanical
Processes.

On Escapements of Watches.

(907.) Although the vibrations of a balance aided by a spring, when uninfluenced by any foreign force, will be perfectly isochronal, yet it is evident from the little weight they possess compared with a pendulum, the heaviest seldom exceeding twenty grains, that they have no means of accumulating such a power over the wheelwork as a pendulum. The execution of the proper escapement for watches is, therefore, a far more difficult and delicate task than in the case of a clock, not only for the above reason, but because the scale upon which it is executed is so much less. To make up for the deficiency of momentum in the balance the weight is accumulated chiefly in the rims, and the vibrations are made very wide and extremely frequent. The balance rim of a middle good watch should pass through at least ten inches in a second; yet with this advantage the momentum is a mere trifle compared with a pendulum; and as Dr. Robison observes, in his elegant Treatise on watchwork, "When we reflect on the small momentum of this regulator, the inevitable irregularities of the maintaining power, and the comparative magnitude even of an almost insensible friction or clamminess, it appears almost chimerical to expect any thing near to equality in the vibrations and incredible that a watch can be made which will not vary more than one beat in 86,400." Yet each have been made, and they must be considered the master exertions of human art.

Watch and
chronome-
ter escape-
ments.

The common recoiling escapement of the old clocks still holds its place in the ordinary pocket watches; but such watches are subject to great variation in their rate of going, by any change in the motive power; which is evident, for if the watch be held backward or pressed forward by the key applied to the fusee, we hear the beating greatly retarded or accelerated. The action of this escapement has been already explained in its application to the pendulum. It is therefore unnecessary to repeat it; but it must be very evident that the maintaining power being applied in the most direct manner, and during the whole of the vibration, that it will have the greatest possible influence in moving the balance; it is therefore remarkable its use is still continued in watches, when those of modern construction, which are equally simple and infinitely superior in their action, can be applied at nearly the expense.

(908.) *Graham's escapement.*—The first improvement of importance that was made in the escapements of watches was by Graham, who introduced the cylinder tooth to act in the same manner as his dead beat in clocks; and which was called the horizontal escapement. In this, as in the dead beat for clocks, the tooth of the scape wheel rests, during the greater part of each vibration, on a cylindrical surface, and acts on the inclined plane, for a short time only, in the middle of each vibration; so that a change in the maintaining power scarcely produces a sensible derangement of the isochronism; for whichever way we turn the key of a horizontal watch, as long as it continues to go, the frequenting of the vibrations is

Graham's
escape-
ment.

Manufac-
tures.

Pl. lxiv.
Fig. 1.

scarcely effected. A drawing of this escapement is given in plate lxiv. fig. 1, where D E represents the rim of the balance wheel; A and C are two of its teeth having their faces formed into planes inclined to the circumference of the wheel in an angle of about fifteen or twenty degrees. Suppose a circular arch A B C described round the centre of the wheel and through the middle of the faces of the teeth. The axis of the balance passes through the same point B of this arch, and we may say that the mean circumference of the teeth passes through the centre of the verge. On this axis is fixed a portion of a thin, hollow cylinder *b c d*, made of hard tempered steel or of some hard and tough stone, such as ruby or sapphire; agates are sufficiently hard but brittle, and chalcedony and cornelian are sufficiently tough but inferior in hardness. This cylinder is so placed on the verge that when the balance is in its quiescent position, the two edges *b* and *d* are in the circumference which passes through the points of the teeth; by which construction it will occupy 210° of the circumference, or 30° more than a semicircle. The edge *b*, to which the tooth approaches from without, is rounded off on both angles. The other edge *d* is formed into a plane inclined to the radius about 30° .

Now, suppose the wheel pressed forward in the direction A C; the point *b* of the tooth touching the round edge will push it outwards turning the balance round in the direction *b c d*; the heel of the tooth will escape from this edge when it is in the position *h* and *b* in the position *i*, the point *b* of the tooth being at *d*, but the edge of the cylinder arrived as far as *i*. The tooth, therefore, rests on the inside of the cylinder while the balance continues its vibration for a short distance, in consequence of the impulse which it has received from the action of the inclined plane. When the vibration is ended by the opposition of the balance spring, the balance returns, the tooth (now in the position B) rolling all the time on the inside of the cylinder. The balance comes back again into its natural position *b c d* with an accelerated motion, by the action of the spring, and would of itself vibrate nearly as far on the opposite side, but is aided again by the tooth, which, pressing on the edge *d*, pushes it aside till it come into the position *k* when the tooth escapes from the cylinder altogether. At this moment the other edge of the cylinder is in the position *b*, and the tooth in the position A. When this vibration in the direction *d c b* is finished, the verge resumes the same position by the action of the spring, and the tooth begins to act on the first edge *b*, pushes it aside, escapes from it, and drops on the inside of the cylinder. In this manner are the vibrations produced gradually increased to their maximum and maintained in that state. Every succeeding tooth of the wheel acts first on the edge *b* and then on the edge *d*, resting first on the outside, and then the inside of the cylinder; and thus the balance is under the influence of the wheels while the edge *b* passes to *h* and while *d* passes to *k*, and the rest of the vibration is performed without any action on the part of the wheels, but is of course a little obstructed by the friction and by the clamminess of the oil, which is however so small, if a little fresh oil be frequently applied, that a timekeeper with a dead beat of Graham has been made which does not vary from true time two parts in a million.

Still, however, the friction of the teeth of the escape wheel on the cylinder or pallet, and the tenacity of the oil where it is employed, may interfere in a slight degree with the time of vibration, especially by the

irregularity to which they are liable. If the friction were perfectly uniform, it would scarcely disturb the isochronism, but friction is always increased by an increase of pressure, hence, therefore, any addition to the sustaining force must tend, in some degree, to retard the vibrations; and to obviate this, the surfaces on which the teeth rest have sometimes been so formed as to create a slight recoil; but this construction does not appear to have been very successful in practice.

(909.) *Duplex escapement*.—The friction is considerably reduced by the duplex escapement, apparently so called from a double series of teeth being employed which is now frequently adopted in pocket chronometers. The teeth of the most prominent series are detained on a cylinder so small as to be unfit for receiving an impulse from them; the balance is therefore impelled by the other series of teeth acting on a pallet a greater distance from the axis. The construction and action will be better understood from the drawing, fig. 2, where A D is the balance wheel, having teeth *f b g* at the circumference. These teeth are entirely for producing the rest, while the balance is making excursions beyond the escapement which is effected by means of an agate cylinder on the verge. This cylinder has a notch *o*, so that when it turns in the direction *o p q* the notch easily passes the tooth in the position B which is resting on the cylindric surface; but when it returns in the direction *q p* the tooth B gets into the notch and is pressed on one side till the notch comes into the position *o*. The tooth being then in the position *b* escapes from the notch, and another tooth drops on the convex surface of the cylinder B.

The balance wheel is also furnished with a set of stout, flat-sided pins standing upright on its rim, as represented by *a D*, and there is also fixed on the verge a larger cylinder C F C above the smaller one *o p q*, with its under surface clear of the wheel, and having a pallet C of ruby or sapphire firmly indented into it and projecting so far as just to be clear of the pins on the wheel. The position of this cylinder with respect to the smaller one below it is such that, when the tooth *b* has escaped from the notch, the pallet C has just passed the pin *a*, which was at A while B rested on the small cylinder, but it moved from A to *a* while B moved to *b*. The wheel being now at liberty, the pin *a* exerts its pressure on the pallet C in the most direct and advantageous manner, and gives it a strong impulsion, following and accelerating it till another tooth drops on the little cylinder. The angle of escapement depends partly on the projection of the pallet, and partly on the diameter of the small cylinder, and the advance of the tooth B into the notch. Independent of the action of the small cylinder, the angle of escapement would be the whole arch of the large cylinder between G and *h*, but *a* stops before it is clear of the pallet; and the arch of impulsion is shortened by all the space that is described by the pin while the tooth moves from B to *b*.

The French have employed a construction somewhat similar to this, termed the *échappement à virgule* or comma escapement, because the pallet resembled a comma in shape. The teeth first rest on a small arch of repose, and then impel the curved surface of a pallet extending to a considerable distance beyond it. In both these cases the single pallet, which is impelled by a tooth of a simple form, requires less labour in the execution than a number of larger teeth, each of which is to be finished with great accuracy; see fig. 6. Somewhat similar to this is Tompion's escapement, fig. 7.

Remontoir
escape-
ment.

Remontoir escapements.—This term remontoir has been applied to escapements in which the maintaining force is applied to the balance by the intervention of a spring which, being bent up at intervals by the maintaining power, acts upon it independently, by which contrivance the balance was considered to be made free and uninfluenced by any change of the maintaining power.

There have been several escapements on this principle invented, the earliest of which was about the year 1600, and is described by Huygens in his *Horologium Oscillatorium*. Harrison employed one in the chronometer which obtained the Parliamentary reward; but the escapement by Mudge appears to have been that in which the principle has been applied with most effect: the following description of it may therefore be interesting.

Mudge's
escapement.

(910.) *Mudge's escapement.*—The basis of this escapement is the old crown wheel and verge, but in place of the verge being in one piece, having two pivots and the balance rivetted on it, let us conceive that each of the pallets of the verge has an arbor and two pivots, and that the balance is on a double-kneed crank, having a pivot at the end of each knee, one of which may be called the foot pivot, the other the balance pivot; the piece of steel from which this last is turned being on the collet on which the balance is rivetted. These pivots and those of the pallet arbors are in one upright line, coinciding and concentric with one another, having their motion free and independent of each other, unless when in these parts of the action of the escapement, the face of the pallets in place of being flat are hollow, or a little curved, having a nib at the edge to lock the wheel by. The reader will better be able to understand the construction, which consists of a considerable complication of parts, by reference to fig. 6, 7, plate lxiii., where A A is the escapement wheel, B B the balance, the verge or axis of which, C C, is a crank; F the upper pendulum spring, by means of which the vibrations of the balance are regulated; G the pendulum spring stud, and H the pendulum spring, which is acted upon by the compensation pieces; D a and E b are two compound pieces which communicate the motion from the balance wheel to the balance, and consist of the following parts, viz., the projections or pallets *l m*, fig. 7, which are acted upon by the teeth of the balance wheel, and were made of black flint in the original timekeeper, but they may be made of ruby, sapphire, or other hard stone; *a* and *b* are steel arms which act upon the pins *c d* of the balance crank; *e* and *f* the impelling springs which are attached to the arbors of the pallets at the inner ends, and to the studs *g* and *h* at the outer ends; *i* and *k* small screws, which fix the pallets to the arbors by means of the clamps or pieces of steel D and E. Having mentioned all the parts of the escapement, we will now endeavour to describe its action.

When the pallet is raised by the balance wheel (as appears in fig. 7) it is kept from going any further by the hook at the end of it, until the pin *d* in the crank meets the arm *b*; for then the crank will carry on with it the arm *b* to the end of its vibration, and at the same time the tooth of the wheel will be disengaged from the above-mentioned hook. Afterwards, as the crank returns, the arm *b*, actuated by its spring *f*, will communicate an impulse to the crank, and soon after its crooked part will rest against one of the teeth of the wheel which again raises the pallet. With respect to the balance wheel, as soon as its tooth is disengaged from the pallet by the means above stated, it raises

the pallet *m*, which, on the returning vibration of the balance, is, by the pin *c* acting on the arm *a*, carried on in a contrary direction, after the manner of the other pallet; and thus the springs attached to the two pallets alternately give their auxiliary aid to the vibrations of the balance.

Mechanical
Processes.

Several other escapements on this principle have been invented; but as their use is entirely supplanted by the escapements generally known by the name of the detached escapements, we conceive it unnecessary to enter into a further description of them, and we complete the article by a full description of the perfect escapements of Arnold and Earnshaw which are now almost invariably used in the best chronometers.

In the Memoirs of the Academy of Paris for the year 1748, and in the collection of approved machines and inventions, we have descriptions of this contrivance, the principle of which, it appears, was first applied to chronometers by Le Roy. The balance wheel rests on a detent, while the balance is vibrating in perfect freedom; it has a pallet standing out from the centre which, in the course of vibration, passes close by the point of a tooth of the wheel. At that instant a pin, connected with this pallet, withdraws the detent from the wheel, and the tooth just mentioned follows the pallet with rapidity and gives it a smart push forward. Immediately after, another tooth of the wheel meets the other clog of the detent and the wheel is again locked; when the balance returns, the pin pushes the detent back into its former place where it again locks the wheel; and the balance again resuming its first direction unlocks the wheel, and receives another impulse from it: and thus the balance is unconnected with the wheels except while it gets the impulsion and at the moment of unlocking the wheels.

Roy's
escape-
ment.

The principle was applied by Mr. Arnold and Earnshaw to the chronometers which were rewarded by the Board of Longitude in the year 1805. The escapements very much resembled each other; the chief difference being that Mr. Arnold employed an epicycloidal tooth acting on a single point of the pallet, and Mr. Earnshaw makes a flat surface of the tooth first act on the point of the pallet, and then the point of the tooth on a flat surface of the pallet. We have given the descriptions of each delivered by the authors, with models of each escapement, to the Board of Longitude, omitting, however, such parts as relate particularly to the model, and are not essential in explaining the principle of the invention.

(911.) *Arnold's escapement.*—A A A, fig. 3, pl. lxiv. represents the escapement wheel, the teeth of which are of a cycloidal shape, and whose upper surface towards the extremity presents to the view a triangular form, two sides of which are described by right lines, and the other by a cycloidal curve, which is the principal part of action.

Arnold's
escape-
ment.
Pl. lxiv.
Fig. 3, 5.

B B *d*, the escapement or locking spring, screwed fast by its end C to a pillar, and extending from C to *d*, in the direction C N *d*. The centre of motion of this spring is between C and N, the part N *d* being more substantial than the part C N.

The locking piece or locking pallet is shown at *a*, whose acting surface is a jewel placed between N and B, and opposite the end of an adjusting screw F, which pallet, descending from the escapement spring, locks upon the interior angle of the tooth 2, (and upon every tooth in succession,) suspending the motion of the escapement wheel A A A for a time, and leaving

Manufac-
tures.

Pl. lxiv.
Fig. 5.

the balance to vibrate without interruption from any part of the machinery. It is to be observed that the triangular parts of the teeth of the wheel *A A A* (the wheel being hollowed or sunk) are raised above the periphery of the wheel to meet the locking piece *a*, so that, upon viewing the wheel edgewise, as in the elevation, (fig. 5,) the teeth will appear broader than the edge of the periphery *b*.

N e is the discharging or unlocking spring which is attached to the escapement or locking spring *B B d* at *N*, and passes (under the adjusting screw *F*) a little beyond the end *d* of the locking spring. This discharging spring is made very delicate and slight.

F is the adjusting screw, supported by the pillar *g*, whose end is opposite to the locking piece or pallet *a*, on the contrary side of the escapement or locking spring *B B d*, and by which the locking piece or pallet *a* may be more or less advanced upon any tooth of the wheel *A A A*, the escapement spring *B B d* always pressing the locking pallet *a* against the end of the screw *F*, except at the time of unlocking the wheel.

o is the unlocking, discharging, or small pallet, whose acting part is a jewel. This pallet, when the balance is in motion, presses against the end of the discharging spring at *e*, and passing on in a direction from *e* to *d*, carries with it for a short space the discharging spring *N e*, and also the locking spring *B B d*, moving them both at the same time, and in so doing carries the locking piece *a* from off the interior angle of the tooth 2, (or any other tooth which may come into that situation,) and leaves the wheel *A A A* at liberty to impart its power to the impelling pallet. But when the balance returns, and the unlocking pallet *o* repasses the discharging spring *N e*, in a direction from *d* to *e*, it does not in the least disturb the locking spring *B B d*, nor consequently the locking piece or pallet *a*, but moves only for a short space the unlocking spring *N e*.

H H H, the impelling or large pallet, whose acting part is at the angle *m*, where a jewel is placed. Upon the exterior of this angle the pallet receives its impulse from the cycloidal part of the teeth of the escapement wheel *A A A*. The circumference of the pallet is incomplete, from a portion being cut away to make room for the action of the teeth of the wheel; through the centre of this pallet *G* a steel axis passes, and is common to the large pallet *H H H*, the small pallet *o*, and the balance.

The impelling pallet *H H H* is supposed in the figure to be vibrating freely from *r* to *S*; here it is perfectly detached, or at liberty from the escapement wheel *A A A*, as will be seen by observing that the unlocking pallet *o* is not in contact with the discharging spring *N e*; nor are either of the teeth 3 or 4 of the wheel in contact with the impelling pallet. The balance or the impelling pallet (for they are both upon the same axis) vibrating from *r* to *S*, the discharging pallet *o* comes in contact with the discharging spring *N e*, (and from that instant it is not detached or free, but in the act of escaping,) and moving it in the direction from *e* to *d*, takes the locking pallet *a* from off the interior angle of the tooth 2, and sets the escapement wheel at liberty for the tooth 3 to act upon the angle *m* of the impelling pallet *H H H*. The tooth 2 will then have passed the locking piece *a*, and the tooth 1 will approach it. The tooth 3 pressing the impelling pallet from *r* to *S*, and continuing to do so until the angle *m* of the impelling pallet and the centre *G* of both pallets form a straight

line. The action of the wheel upon the pallet continuing until the point of the tooth 3 is about to quit the angle *m* of the impelling pallet, the tooth 2 approaches nearer to the circumference of the same pallet, and tooth 1 advances toward the locking piece or pallet *a*, against which it falls, and is held fast as soon as the end of the tooth 3 quits the impelling pallet. Here the act of escaping ends, and the impelling pallet is again detached or unconnected with the wheel, and moves in free vibration for a certain number of degrees, until it is returned by the power of the balance spring, and repasses from *S* to *r*, still independent of the escapement wheel, or of any thing else, except the very little resistance which is encountered by the discharging pallet *o*, in repassing the discharging spring *N e*, which it does without disturbing the locking piece *a*, or consequently the escapement wheel, and continuing for a certain number of degrees is again returned by the balance spring from *r* to *S*, when, resuming its situation as in the figure, it is prepared to act as before.

It may be proper to remark that the action of the cycloidal tooth upon the impelling pallet is always the same in the beginning, in the middle, and at the end of its motion, impelling the pallet with the same quantity of surface in action at all times, and at all times equidistant from the axis of the pallet.

(912.) *Earnshaw's escapement*.—The principle of this escapement, as we have before observed, is the same as in that just described; as, however, there exists considerable practical differences which are considered of considerable importance, we give, as in the former case, such parts of the author's description sent to the Board of Longitude as are necessary to point out the construction and action of the instrument.

A B C D, fig. 4, is the escapement wheel, and the small wheel *M S K* is the large pallet, which is a cylindrical piece of steel, having a notch or piece cut out of it at *l h r*; against the side of this notch is a square flat piece of ruby, or any hard stone *h l*, ground and polished very smooth, and fixed fast into the pallet. The cylinder is so placed with respect to the balance wheel that it may not be more than just clear of two adjoining teeth. *E F* is a long thin spring, which is made fast at one end by being pinned into a stud, and made to bear gently against the head of an adjusting screw *m*, the other end is bent a little into the form of a hook; to this spring there is fixed another very slender spring at *G*, which projects to a small distance beyond it. This small spring lies on the side of the thick spring nearest to the balance wheel. Upon the spring *E F* there is fixed a semi-cylindrical pin, which stands up perpendicular upon it, and of a sufficient length to fall between the teeth of the balance wheel *A B C D*. This pin is called the locking pallet, and is placed on the opposite side of the spring represented to view. Through the centre of the cylindrical pallet *M S K* a strong steel axis passes called the verge; the pallet is made fast to this axis, which also passes through the centre of the balance, and is made fast to it; it has two fine pivots at its extremities, upon which it turns very freely. A little above the cylindrical pallet *M S K* (as appears in the figure) is fixed a small cylindrical piece of steel *i n*, having a small part projecting out at *i*; this is called the lifting pallet: it fixes upon the verge like a collar, and is made fast by a twist, so as to be set in any position with respect to the large pallet *M S K*. The end of the long spring *E F* being made very

Mechanical

Manufac-
tures.

slender, if a small force be applied at the point *o* to press that end out from the wheel *A B C D*, it easily yields in that direction, turning upon a centre at *G*; it is also made to slide in a groove in this stud, in such a manner that the end *o* may be placed at any required distance from the centre of the verge.

Having described the several parts as they appear in the figure, we next come to their connection or situation with respect to each other. Let the long spring *E F* be supposed to be placed so that the end of the slender spring *G i* may project a little way over the point of the lifting pallet *i n*, but not so close but that the point of the pallet may pass by the hooked end of the spring *E F* without touching it; the head of the adjusting screw *m* is also supposed to bear gently on the inner side of the spring *E F*, or that nearest to the wheel, and at the same time the locking pallet is so placed that one of the teeth *D* of the balance wheel may just take hold of it. This pallet is not visible in its proper place in the figure, being covered from sight by the screw *m* and part of the spring *E F*; its position is therefore represented by the dot *k*, on the opposite side of the wheel, having the tooth *A* just bearing up against it. From the above description of the several parts of the escapement, and their connection with each other, it will be easy to see the mode of its action, which is as follows:

A force being supposed to be applied to the balance wheel, so as to cause it to move round in the direction of the letters *A B C D*, one of the teeth, as *D*, will come up against the locking pallet, (as represented at *A*, and the locking pallet by *k*.) The wheel is then said to be locked, being prevented from moving forward by this pin. Let the balance be now supposed to rest in its quiescent position, and it will have the situation represented in the figure; the lifting point *i* of the pallet *i n* will be just clear of the projecting end of the slender spring, the face *h l* of the large pallet *M S K* will fall a little below the point of the tooth *B*, and remains perfectly at rest in this position. Now as the balance is carried a little way round in the direction of the letters *K M S*, by this motion the end *i* of the lifting pallet *i n* will be brought to press up against the projecting end of the slender spring, and as this spring is fixed on the side of the spring *E F* nearest to the balance wheel, the point *i* will press the two springs together out from the balance wheel; then, as only the point of the tooth *D* (see its position at *k*) touches the locking pallet when the spring *E F* was at rest against the head of the screw *m*, it will, by the spring being pressed out from the tooth, be now in the position *a*, clear of the tooth *A* of the balance wheel; the wheel being at liberty will move round by the force supposed to be applied to it; but as the point *i* of the large pallet moves on and presses out the spring, the point *l* approaches towards the point of the tooth *B* of the balance wheel, so that when the spring *E F* is sufficiently pushed out to unlock the wheel, the point *l* of the large pallet will be got to *d*, and in this position the point of the tooth *B* will fall upon it, and at the same time the point of the tooth *D* has just dropped off from the locking pallet *m*; the force of the wheel being by this means applied to the top of the pallet *h l* gives an increased momentum to the balance, and assists it in its motion in the same direction, and by the continued motion of the large pallet in the direction *M S K*, the point of the tooth *B*, which keeps pressing and urging it for-

ward, moves up towards the bottom of the face of the pallet towards *h*, until the plain flat surfaces of the tooth and pallet come into contact; by this time the end of the slender spring has dropped off from the point *i* of the lifting pallet, and the two springs have returned again into their quiescent positions, the spring *E F* gently bearing against the head of the adjusting screw *m*, and the locking pallet in a position to receive the next tooth *C* of the balance wheel. When the two surfaces of the tooth and pallet are thus in contact, the greatest force of the wheel is exerted upon the pallet, and of course upon the balance moving with it. The tooth still pressing against the face of the pallet, and the pallet moving in the direction *M S K*, it at last drops off, leaving the balance at perfect liberty to move on in the direction in which it was going. Just as the point of the tooth *B*, which has been pressing the large pallet round, is ready to leave it, the next tooth *C* of the wheel is almost in contact with the locking pallet *m*, so that the instant the tooth *B* drops off, the wheel is again locked, and the action of that tooth upon the balance is finished. As the balance moves with the greatest freedom upon its pivots, the force of the tooth has given it a considerable velocity, so that the balance still keeps moving on in the same direction; after the pressure of the tooth is removed by slipping off from the pallet, until the force of the pendulum spring being continually increased by being wound up overcomes the momentum of the balance, which, for an instant of time, is then stationary, but immediately returns by the action of the spring, which exerts a considerable force upon it in unwinding itself. As the balance returns, the point *i* of the lifting pallet *i n* passes by the ends of the two springs *E F* and *G i*, and, in passing by, pushes the projecting end *o* of the slender spring in towards the balance wheel, until it has passed it; which, as soon as it has done, the projecting end again returns and applies itself close to the hooked end of the spring *E F* as before. The spring *G i* is made so slender that it gives but little resistance to the balance during the time the point *i* of the lifting pallet is passing it, and of course causes but little (if any) decrease in its momentum. During the time the point *i* of the lifting pallet is passing the small spring, the long spring *E F* remains steadily bearing against the head of the adjusting screw *m*, as the hooked end just lets the end of the lifting pallet pass by without touching. As the spring has now been continually acting upon the balance from the extremity of its vibration in the direction *M S K*, it has given it the greatest velocity, when the point *i* of the lifting pallet is passing the end of the slender spring; for at this instant the spring, which was wound up by the contrary direction of the balance, is now unwound again, or in the same state as it was in its quiescent position at first, and of course has no effect upon the balance at all in either direction; but the balance having now all the velocity it could acquire from the unwinding of the spring, goes on in the direction *S M K*, until the force of this spring again stops it and brings it back again, moving in the same direction as at first with a considerable velocity. By this return of the balance, the point *i* of the lifting pallet comes up again to the projecting end *o* of the slender spring, pushes back the long spring *E F* and unlocks the wheel, and another tooth falling upon the face of the pallet *h l* gives fresh energy to the balance, and thus the action is carried on as before.

We have preferred entering at length upon the

Cutlery and Hardware Manufacture.

(914.) The making of edge tools and cutting instruments, commonly denominated cutlery, a branch of the more general denomination of hardware, forms an important branch of English manufactures, but it is one less dependent on machinery than almost any other, and, therefore, does not fall so immediately within the province of the present Work. We cannot, however, allow it to be entirely passed over without notice. All the various sorts of cutting tools, as plane-irons, chisels, saws, knives, &c., require peculiar qualities, and are commonly separate branches of the cutler's trade; and the perfection of workmanship, tempering, &c., being the result of long and continued practice, could not be communicated in writing if even the parties were more disposed than they are to divulge their respective processes. We shall, therefore, attempt only a few general remarks.

Three different kinds of steel are used by cutlers, *i. e.* the blistered, shear, and cast steel. The first named is employed in the coarser and cheaper articles; the shear steel is used for all such edge tools as require great tenacity without much hardness, such as table knives, plane irons, scythes, &c.; cast steel is employed only in the manufacture of instruments requiring very fine edges, as surgeons' instruments, the better sort of razors, &c.

Historical Sketch of the Hardware Trade.

(915.) The following abstract from the Report of the Parliamentary Committee on the Hardware Trade will show its extraordinary increase during the last half century. Historical sketch.

Before the year 1780 there were probably fabricated in Sheffield nearly all the principal descriptions of goods which are now made, although of course in much more limited quantities. In the eighth edition, published in 1778, of the *Tour through the Island of Great Britain*, originally written by Defoe, we find the following account of the manufactures then carried on:—"The principal manufactures here are knives, forks, scissors, razors, lancets, phleams, files, edge-tools for carpenters, shears, &c., metal and horn buttons; and of late years various kinds of goods have been made plated with silver, such as knives, buttons, buckles, snuff-boxes, tweezer-cases, toothpick-cases, saucepans, coffee-pots, cups, tankards, candlesticks, &c. There is likewise reason to believe that here were first made snuff-boxes, candlesticks, &c., of a sort of coal called kennel, or channel-coal, formerly got near this place." Saws, indeed, the manufacture of which is now so important a branch, are not mentioned in this list of articles; but the omission is probably accidental. The amount of plated manufacture, both in Sheffield and Birmingham, had before this become so considerable that, in 1772, an

Manufactures.

Act of Parliament was passed appointing wardens and assay-masters for both towns.

The information on the subject of the present state of the manufactures and trade of Sheffield, to be found in the Report of the late Committee of the House of Commons, was principally obtained from two witnesses, Mr. Samuel Jackson, manufacturer of saws and steel, and exporter of hardware generally, and Mr. John Milner, who has spent the greater part of his life as a journeyman spring-knife cutler, but is now a manufacturer on his own account. This Report is of considerable length, and we avail ourselves of a very judicious abstract from it given in a useful statistical Work, published monthly, entitled *A Companion to the Newspaper*. It takes first a concise view of the present state of the hardware and cutlery manufactures in America and on the Continent, which we also give for the sake of the subsequent comparisons.

The declared value of the entire British and Irish produce and manufactures, exported to all parts of the world, is above thirty-six millions sterling; and in 1831, above nine millions, or about a fourth part of this sum, was the amount exported to the United States of America alone. Mr. Jackson states incidentally that one-fourth of the whole goods manufactured in Sheffield are exported to the United States. Considering the unquestionably large extent of the home consumption of Sheffield goods, we should think this a high estimate; but it appears from an account in the second volume of the Tables published by the Board of Trade, that of the whole British cutlery and hardware exported, the United States take rather more than one-half. The declared value of the whole quantity exported in 1832, was £1,433,297; of which the share of the United States was £738,015. Of the goods manufactured in Sheffield, indeed, there is but a very small portion exported to the Continent; the chief markets being in this Country and in America. Owing to the political agitation in the United States throughout the whole of the last year, (1833,) there was a great falling off both in the spring and in the autumn orders from that quarter; and Sheffield severely felt the effect of this suspension. We fear the new commercial difficulties which have resulted from the interference of the President with the National Bank must still for some time prevent the demand from rising to its former average. Mr. Milner says, "We are too much dependent upon the American market; should any thing unpleasant take place between America and England, we should be in a very bad state, for the experience of the last year and a half has shown the people of Sheffield, that if a convulsion took place in America, or if an alteration should take place in the commercial policy of America, Sheffield might be ruined." Fortunately, there is but little hazard of the occurrence of any one of the three calamitous events to which the apprehensions of the witness are directed. Of all insane wars that were ever undertaken, a war between two Countries, one of which, to mention no other bonds of union, is a customer to the other for not less than one-fourth of the whole amount of goods which that other annually has to dispose of, would assuredly be the most insane. The worst of the political agitation which has for some time interrupted the tranquillity and prosperity of the United States is also, it may be hoped, now over. And as for any alteration of the commercial policy of that Country, the only alteration which is now likely to take place is one that will be favourable to British inter-

rests, as involving a still further relaxation of the system by which the introduction of foreign manufactures has been hitherto attempted to be checked. Mr. Jackson, who has visited the United States, found some small manufactories of fine cutlery there; but owing, he says, to the high price of labour, they could not compete with the English. In consequence of the protection afforded by the former tariff, they had made some progress in the fabrication of some of the heavier kinds of edge-tools, and also in that of mill-saws, upon which a duty of one dollar each was paid, amounting to about fifty per cent. on the value; but their success was confined to these articles.

The declared value of the entire British hardware and cutlery exported, which in 1832, as already mentioned, was £1,433,297, was in 1831, £1,620,631. The difference was probably mainly produced by the falling off in the orders from America. The quantities exported in the two years were, in 1831, 16,799 tons, and in 1832, 15,294 tons. In the latter year the number of tons exported to each of the Countries, taking the largest quantities, was as under:

	Tons.
To United States of America ...	7874
British North America	1549
Asia	1032
British West Indies	667
Mexico and South America .	616
Germany	586
Foreign West Indies	560
Brazil	497
Italy	341
Africa	314

Smaller quantities were also sent to Russia, the Netherlands, France, Spain, and the Canaries, the Isles of Guernsey, Jersey, Alderney, and Man, Portugal, the Azores, and Madeira, Turkey and Continental Greece, Denmark, Gibraltar, Prussia, Malta, Norway, the Ionian Islands, Sweden, and the Morea and Greek Islands.

As to the continental manufactures, Mr. Jackson states, that in Prussia, Belgium, and France, a great many species of hardware trades are carried on, and several of them to a much greater extent than in Sheffield. Many are of recent origin, but others existed before there were similar manufactures in Sheffield. In repeated visits which he made to the Continent, this witness found the hardware manufactures constantly improving. The branches that appeared to be making the greatest progress were the scissors, saw, edged-tool, and steel manufactures; and the places in which these branches were carried on most successfully were the Duchy of De Berg in Prussia, Remschorld, Solingen, and that neighbourhood, and different parts of France. "In France especially," says Mr. Jackson, "many large manufactories have sprung up of late years, in consequence of the encouragement given to them by government, and by anonymous Societies with large capital, and they have been much protected in consequence of the prohibitory duties upon English manufactures." The operatives belonging to the French manufactories are described as very inferior to the operatives in England, in regard to both their comforts and their earnings. One of the greatest of the French manufactories is that at Molsheim, near Strasburg. "At this manufactory," says Mr. Jackson, "where they employ as many hands

Mechanical Processes.

Manufac-
tures.

in the manufacture of saws almost as they employ in Sheffield, the wages of labour are as twelve to one; that is to say, we have to pay for a single article as much as the manufacturer at Molsheim pays for a dozen. These observations were made by myself at the time of my last journey, (in the autumn of 1830.) Being a practical man, I took more interest in ascertaining the relative situation of the operatives in the two Countries. I will state, from the remarks I made, what I ascertained to be the usual terms of employment. A saw-grinder at Molsheim earns about 28 sous, or 1s. 2d. a day; he grinds and glazes six dozen billet webs, (that is a species of web of which large quantities are sent to America,) which makes the price 2½d. per dozen. The Sheffield price for the same work, not done in a superior manner, is 2s. 6d. per dozen." At this, which is the present rate of payment, the Sheffield workman would make from 15s. to 20s. per day. But wages were, some years ago, considerably higher; and "we have had workmen," says the witness, "that have earned 20s. on a Saturday morning before breakfast, when perhaps they had not worked the previous part of the week." This happened about 1810. A saw-maker at Molsheim, Mr. Jackson afterwards states, works in summer from five in the morning to seven in the evening; and in the winter from six in the morning to eight in the evening. The prices of provisions he found to be there as follows: household bread 1d. per pound; white bread 1½d. per pound; beef 3d. per pound; potatoes 2d. per peck; beer 1d. per pint. "In the Duchy of De Berg, in Prussia," he proceeds, "there is also a large manufactory of steel, saws, files, edged-tools, and cutlery; there are 800 saw manufacturers, 1000 file manufacturers, 3000 cutlers, 1000 sabre manufacturers, 1500 scissor manufacturers. A master saw manufacturer has generally three or four workmen who board and lodge in his house, and who receive, besides board and lodging, from 2s. to 2s. 6d. per week; without board and lodging, good workmen will obtain from 1s. 2d. to 1s. 3d. per day, and work from five in the morning till nine in the evening." These long hours, namely, from five in the morning till seven or nine in the evening, are stated to be general throughout the Continent; and the men, besides, appeared to Mr. Jackson to work much harder during that time than they do in England. There is very little intemperance among them. The prices of provisions in the Duchy of De Berg are, black bread, made of rye coarsely ground down, ½d. the English pound; white bread 1½d.; and meat 3½d. It is here that the articles are manufactured which principally come into competition with English goods in America. They cannot on the Continent make the circular saws, nor the hand saws, nor the back saws, nor long saws, so well as they can be made in England; but other kinds, including those which are chiefly in demand on the Continent, and in the American market, they can make fully as well as we can. The principal continental market where the French come into competition with us is that of Belgium. The people of that Country are supplied with certain kind of saws by the French manufacturers, and with other kinds by the English.

The finer descriptions of surgeons' instruments made at the manufactories of Paris, Mr. Jackson thinks inferior to those made in England, while the price is higher. "The reputation of English edged-tools," he says, "of files and saws, steel and razors, is very great throughout

France." English cutlery is occasionally smuggled into that Country through Belgium. It is believed, however, that of late years this had not been done to any considerable extent. With the exception of a pen-knife or a razor, there is little or no English cutlery to be seen in private families in France. The shops of the Palais Royal exhibit what they call English goods, but there is reason to believe that most of them are manufactured in the Country, and then impressed with the English marks, that they may bring a higher price. On the other hand, some of the finer articles of cutlery are occasionally brought from France to this Country; for example, scissors fitted with mother-of-pearl or ivory shanks, of which the workmanship is both cheaper and better than we can produce in England, although the blades are considered inferior.

As to the wages, and the comparative condition of the workmen in the two Countries, Mr. Jackson states the following facts: "The present price of provisions in France (in June 1833) is nearly the same as in England. A very intelligent French gentleman, who visited Sheffield last week, as the representative of a society just formed at Lyons, who are expecting to be large purchasers of foreign goods, gave me the price of provisions at Lyons and the neighbourhood at this moment; the price of bread, what is called *pain de menage*, is about 3 sous per pound; the price of meat from 10 to 12 sous. The cost of a house for a workman and his family—a house containing three rooms—would be from £5 to £6 per year, which is as nearly as possible the price at Sheffield. At Paris, the prices would be dearer." The wages in France vary from a franc and a half to three francs a day. In Sheffield, the operatives in the cutlery trade work eleven or twelve hours a day, and, in the different branches, were receiving in June last the following wages: of the spring-knife cutlers, the blade forgers from 21s. to 31s. 6d. per week; the workboard hands (those who put the knives together) from 15s. to 25s.; the grinders from 30s. to 40s.; of the table knife-cutlers, the forgers from 21s. to 35s.; the hafters from 18s. to 27s.; the grinders from 27s. to 40s.; of the razor-makers, the strikers from 24s. to 26s.; the hafters from 18s. to 40s.; and the grinders from 18s. to 50s. These were the wages for a full week of six days; but there might then be from 200 to 300 operatives not having more than two or three days work a week; and, of the whole number of operatives, probably not more than half were in full employment. The number of hands actually employed in each of the principal staple trades of Sheffield was as follows: makers of table-knives and forks, 3689; of pen and pocket-knives, 2680; of razors, 754; of scissors, 600; of files, 1768; of saws, 563; of edged-tools, 703; of stove-grate fenders, &c., 1530; of white metal articles, 643; and of silver-plated goods, 500; making a total of 13,430. There are, however, some other hardware manufactures carried on. The witness thinks that the workmen, at the present moment, owing to a variety of causes, do not receive the same amount of money for their work which they did thirty years ago; but still he is of opinion that their comforts are pretty much the same, and that they never either lived or dressed better than at present. "From what I have seen," he says, "of the manufacturers of England, I believe the workmen in Sheffield are better clothed and better fed, and live in better houses than the workmen in any other part of the country, or in any other part of

Mechanical
Processes.

Manufac-
tures.

the world." As to the French workmen, he represents them as miserable beyond description, as compared with the English. In certain branches of the business, too, which have been only recently introduced into France, he states that an English workman will produce more in a given space of time than a French workman. A good many British artisans have gone over to be employed in the continental manufactories, but most of them have very soon returned home. "In starting a fresh manufactory," says Mr. Jackson, "it is universally the practice, particularly in the iron trade, to employ a few Englishmen; but after their own workmen have obtained the same skill and knowledge which the Englishmen possess—the prices of English workmen being much higher than that of native workmen—it is of course the interest of the manufacturer either to expect the former to come down to the prices paid to the latter, or to let him return to his own Country. I am acquainted with Mr. Cockerill, a large manufacturer at Liege and Seraing, and when he commenced his manufactory, he employed a great number of English workmen, but I believe most of them have now returned to England. He had to pay for English workmen 7s. and 8s. a day, and his native workmen are employed at one and two francs a day."

Mr. Mil-
ner's evi-
dence.

Mr. Milner's evidence, although it does not perhaps contain any facts irreconcilable with the statements of Mr. Jackson, yet presents a more gloomy picture of the general condition of the workmen than that drawn by the latter gentleman. This witness says, that about 1817 a decline of prices began to take place, which has been going on ever since, and that from 1818 the circumstances of the workmen began to be sensibly operated upon. Employment has since been so irregular, that there never has been a sufficiency of it for more than a year or two at a time, and there has frequently been not half work for the entire number of hands. The destitution and misery of many of them on these occasions are described as being very great. Mr. Milner conceives that, upon the whole, the workmen now consume a great deal less than they did fifteen or sixteen years ago, both of such articles as tea, sugar, and coffee, and also of butcher's meat. Their dress he likewise thinks is much inferior to what it was formerly. It is evident, however, that, in judging of matters of this kind, people almost always proceed in great part upon mere general impressions, rather than upon a careful induction and sufficient examination of facts. There can be no doubt that wages have fallen considerably since the termination of the war, in the cutlery, as in all other trades; but it is by no means made out that the prices of provisions, and of the other necessities and comforts of life, have not declined in at least an equal degree. It is also beyond all question that the market for the hardware manufactures of this Country has of late years been greatly extended; and the quantity of employment upon the whole, therefore, must be much greater than it formerly was. We should think that this augmentation of the demand has fully kept pace even with the increase in the numbers of the workmen. Owing to circumstances, however, some of which at least are altogether beyond legislative control, the trade may not for the last twenty years have been so steady a one as it was for some time before; and, whether this may have been the case or not, of course, when a stagnation does take place, the number of sufferers is now greater, and the

sum of misery produced more frightful, than when the entire number of the persons connected with the business was only half or three-fourths of what it now is. A fact stated by Mr. Jackson should go a great way to prove that Mr. Milner's comparison of present with former times is to a great extent delusive. The poor-rates of the parish of Sheffield, it seems, in 1810 were £38,000, and now they do not amount to £20,000; a reduction which, even after making allowance for the rise in the value of money, cannot be regarded as less than fifteen or sixteen per cent. If we take it, as we ought to do, in connection with the increase of the population, (which since 1811 has risen from 53,000 to 92,000,) it is a real reduction of between fifty and sixty per cent. In other words, the pauperism of Sheffield is not now half so great as it was in 1810; yet at that time wages were higher than they have ever been since.

Mechanical
Processes.

Of late years, machinery has been introduced to some extent into the cutlery business in England, which has considerably reduced the cost of production in the case of certain articles. About ten or a dozen years ago, for instance, as Mr. Jackson states, to manufacture a three square file, it was necessary to forge it out of a square bar, but now, by the aid of machinery, the bar of steel is rolled three square. The witness found no rolling-mills for this purpose at the manufactories in the Duchy of De Berg. Of the different branches of the trade as carried on in Sheffield, the manufacture of scissors and that of plated goods appear to be in the greatest state of depression; or rather, they are the only branches that are depressed from any cause except the temporary diminution of the foreign demand. In the scissor trade, according to Mr. Milner, there were at one time between 300 and 400 forgers; and at present there are only about 170. To make up, however, for the falling off in the manufacture of wrought-steel scissors, there are now very large quantities of cast scissors manufactured in Sheffield. The latter is a very inferior article, but is so difficult to distinguish from the former by the eye, that cast scissors are often imposed upon the Public for those made of wrought steel. Mr. Milner is of opinion, and he says such is almost the universal impression, that the trade of Sheffield has been very much injured by the loss of reputation arising from this substitution of a spurious for a genuine article. Meetings have been held to devise some means of remedying the evil; and it has been proposed to incorporate the manufacturers of wrought-steel articles, and to allow them to stamp their goods with some common mark, which should be effectually protected; but no measures have as yet been taken to carry that plan into effect. Previously to 1814, it seems, no person could manufacture without taking out what is called an incorporated mark; but since that time, in consequence, as we understand the witness, of some change in the law, any person is allowed to use the mark of the Corporation of cutlers who chooses, and to place it on any description of goods he may find it convenient to manufacture. We may here mention, by the by, that of what is called town-trade, or London cutlery, there is, according to Mr. Jackson, very little really made in London. Notwithstanding the law to the contrary, he conceives it is not unusual even for the word London to be stamped upon many articles made at Sheffield. There may be some very fine and expensive cutlery made in the metropolis, but the greater part even of that description of articles must come

Manufac-
tures.

from Sheffield, from the greater cheapness of labour there. The witness mentions another fact connected with this matter. "Nearly all the Sheffield manufacturers," he says, "are obliged to strike the name of their customers upon their wares, and that is one reason perhaps why no cutlery manufacturers in Sheffield can keep stocks, as they are uncertain who their customers may be; and, as articles of hardware cannot be marked well after they are hardened, they are deterred from having a quantity made on hand till they have orders, to see what impression they are to bear." There appears to be no good reason why this inconvenient custom should be continued. As for plated goods, Mr. Jackson is of opinion, that people do not now buy as many articles of that description as they used to do; but the principal cause of the falling off in this branch of business at Sheffield appears to be, that it has partly migrated to Birmingham, where wages in some departments of it are only one half what they are at Sheffield. On the other hand, the file trade has nearly left Birmingham, in consequence of Sheffield having superior advantages for the manufacture of that article. Upon the whole, Mr. Jackson admits, what, indeed, must be considered quite indisputable, that cutlery is now consumed in this Country to as great an extent as it ever was; but the goods used, he says, are lower priced goods, and he seems to intend that we should understand goods of an inferior description. That more of such goods are now manufactured than formerly, we believe; but we believe, too, that the consumption of the better descriptions of goods also has increased, and that they, as well as the others, although no doubt at lower prices than formerly, are manufactured in greater quantities than ever.

That the hardware trade is upon the whole in a tolerably prosperous state, is proved by the admissions of the witnesses. The fall of prices in Sheffield goods since the Peace is asserted by Mr. Jackson to have been greater than from thirty to forty per cent.; but he also says, "If we may judge from the apparent circumstances of the manufacturers, there does not appear to be much more distress than there was formerly." It is acknowledged also, that the town has probably increased more than any other in England, both in population, and in the number of its manufacturing establishments. When asked if the manufacturers and merchants have been doing as well of late years as during the War, this witness answers, "We have had many merchants who have obtained very considerable property, though business is done at low profits." The trade for the last eighteen or twenty years has, it is stated, been carried on nearly all on orders; and, indeed, with the exception of a few remarkable years, there appears never to have been much of what is called speculation among the Sheffield manufacturers. It is said, accordingly, to have been ascertained, that there are fewer failures among them in proportion to their number, than among the manufacturers or merchants of any other part of England. Periods of depression in the hardware trade, indeed, appear to have occurred occasionally of late years, though not almost every second or third year, as Mr. Jackson loosely states. There was a great depression in 1816, and again in 1822; but since the latter of those years, although prices have generally been lower than they were previously to 1827, it is not pretended that there has been any stagnation till that occasioned by the late interruption of the usual demand from the United States. Mr. Jackson,

when asked if he would recommend a friend with capital in his pocket, and competent knowledge and industry, to embark in the Sheffield trade at present, replies, that the competition is so great that a person must have a perfect knowledge of the business in order to succeed in it; but when further asked if, should his friend have good capital in his pocket, he would rather recommend him to keep it there; his answer is, "I should think that most of the manufacturers fancy that they can employ their capital better in trade than by keeping it in their pocket." A manufacturer, he states also, who wishes to retire from business, can at present easily withdraw his capital. That is to say, the trade is in so fair a state, that more capital flows freely into it to replace whatever is taken out. Many of the branches of the hardware manufacture, however, may be carried on without much capital. There are some manufactories in Sheffield that have cost £30,000, or £40,000; but since 1817, according to Mr. Milner, a change has to a considerable extent taken place in the mode of conducting the trade, many persons having then commenced manufacturing without any capital, and their number having gone on increasing ever since, "so that now," as the witness assures us, "by far the greater portion of the cutlery business, and especially the spring-knife business, is conducted by men of this description."

Two witnesses connected with the business of brass-founding were examined by the Committee: Mr. John Dixon, of Wolverhampton, and Mr. Thomas Clutton Salt, of Birmingham. Their evidence extends over nearly thirty folio pages; and we can afford to notice only a few of the more important among the facts to which it refers. Indeed, by far the greater part of it is made up merely of strong expressions of belief and opinion, in support of which no well-ascertained facts are adduced. Both witnesses draw the picture of the existing state of the trade in the darkest colours. Both masters and workmen, according to their representations, are suffering to an extent which scarcely any former period has witnessed. Their favourite era of comparison, or rather of contrast, with the present times, we observe, is the years 1824 and 1825. Mr. Salt states that a capital of £10,000 then easily yielded him an annual profit of £3000. We submit that such returns as this could not be expected to continue. The truth accordingly appears to us clearly to be, that the depression under which the greater manufacturers are now suffering is merely the natural consequence and penalty of the extravagant trading of that former period. It is impossible to believe that the consumption of the articles of their manufacture has diminished, or the demand for them really fallen off within the last twenty years. No man can open his eyes and look around him without being convinced that this is not the case. We may mention merely lamps for domestic use, and gas burners and other fittings, as articles made wholly or partly of brass which must have created an almost entirely new demand within the period that has been mentioned. The witnesses admit that they cannot point out any instance of the least importance in which another material has of late years been generally substituted for brass. It is scarcely possible, therefore, to doubt that the manufacture of articles of brass is really now much more extensive than it was twenty years ago. It may be, however, that the quantity of goods annually made since 1825 has not since reached the amount to which it was carried in that and

Mechanical
Processes.

Mr. Dixon's
and Mr.
Salt's evi-
dence.

Manufac-
tures.

the preceding year. The glut of the market then produced must in this, as well as in other businesses, have left a pressure which would continue to be felt for years. Accordingly, in order to meet this state of things, the aim of the manufacturer is now to reduce his stock as much as possible. Mr. Salt states, that he used to keep an average £6000 stock, but that now he never allows it to be above £1500. The efforts made with this object must, of course, have tended still further to reduce the annual production below what it was before 1825. But the change in the mode of managing the trade is in every way a beneficial one to the manufacturer. He is, in the first place, pursuing by far the best course for speedily relieving the market, and restoring the fair and full effect of the natural demand. And, secondly, while doing this, he is also unlocking a large amount of capital, and by that means carrying on his manufacture at much less cost than formerly. The prosperity of 1824 and 1825, however, when the brass founders were making an annual profit of thirty per cent. upon their invested capital, has likewise had the effect of attracting many new adventurers into the trade, and, by thus over-crowding it, opposed an additional difficulty in the way of its restoration to a healthy state. Both the witnesses speak of the numbers of persons formerly journeymen, who of late years have set up as manufacturers, and who, having little or no capital, and employing few hands, are either able, or are compelled by their necessities, to sell their goods at a lower price than that for which they can be produced by the larger establishments. Whatever is unsound, however, in this state of things, must also soon cure itself and pass away.

The fall in the prices of brass-foundry articles in the last fifteen years is, according to Mr. Dixon—who manufactures chiefly handles and the articles for plumbers, and not the finer descriptions of goods—more than 50 per cent. The nominal prices are indeed the same as they have been for twenty years; but, according to the practice of the trade, the sales are made always subject to certain discounts; and the discount which was formerly 20 per cent. is now 50. This fall, however, will not, as Mr. Dixon reckons, make a difference of 50 per cent. He says, correctly enough, "If we take 20 per cent. from 20s., it leaves 16s.; but if we take 50 per cent. it leaves us only 10s., consequently we have but 10s. instead of 16s." But it is not true that this, as he adds, makes more than 50 per cent. difference to the manufacturer. Taking the fact to be as stated, the manufacturer, where he formerly received 16s., now receives 10s., which implies only a fall of prices to the extent of not quite 38 per cent. The high prices referred to in this calculation are those that were obtained from 1819 to 1826.

To compensate this fall of prices, however, there has been a fall both of wages and of the price of the new materials. Of the latter, the principal is copper, which used to cost £112 per ton, and may now be purchased for £83. From this circumstance alone then we have a saving in the cost of production to the extent of 26 per cent. Lead also, another of the materials, which has been as high as £24, is now only £14 per ton; and spelter, which was £27, (a doubt is expressed if it was not a good deal higher,) now costs only £14 or £15. Mr. Salt complains of it as a disadvantage, that, whereas formerly it was the practice for the manufacturers in Birmingham to make all their purchases the first twelvemonth without paying any thing, and only to clear off

Mechanical
Processes.

the debt in the course of the second twelvemonth, they are now obliged to pay down cash for all the metal they require. But the change, while it has certainly introduced a wholesomer state of trade upon the whole, is really, in its direct and immediate operation, most beneficial to the manufacturer, who, for the long credit which he formerly enjoyed, used to pay no less than £1 per month on the ton; that is to say if he purchased a ton of copper at £112, and did not pay the money for a year after, it cost him actually £124. At present he gives his banker's bill for the metal, with only such a difference as may cover the discount.

The fall of wages since 1819 or 1820 is stated by Mr. Dixon to have been from 5 to 20 per cent. Wages now range from about 15s. to 25s. per week, and the average may be about 20s. Till 1825 it was about 27s. or 28s. This, by the by, would imply a fall of nearer 30 than 20 per cent. Afterwards the witness states, that to some of his men he still gives 35s. per week. They would have had two guineas before 1825. All this, however, is merely a calculation of what the men generally earn, or what they may earn; for they actually work by the job or piece, and not for weekly wages. The manufactory is opened at six in the morning, and they are allowed to work during what part of the day they please, till eight at night, when it is cleared, and the doors locked. Mr. Salt however states, that though he continues to pay the men who have been a long time with him from 24s. to 30s. a week, he gives no more than from 8s. to 11s. to his new hands; and he says he is sure he could in the course of a day get a 1000 men, all skilful artisans, to work for him at 6s. a week. Boys and women are now employed to do many parts of the work which the men used to execute. At Wolverhampton, also, it is stated, there are a vast number of females employed in the tin and japan trade, and in the screw trade. No machinery whatever has been introduced in the fabrication of such articles as those which Mr. Dixon furnishes; and that used in the department of the trade with which Mr. Salt is connected—the manufacture of lamps and ornamental brass-foundry in general—has not of late years been materially improved. It is well known, however, that owing to the introduction of steam as a moving power, even the old machinery now performs its functions much more economically than formerly. A remarkable instance of this is mentioned by Mr. Babbage in his *Work on the Economy of Machinery and Manufactures*. "Twenty years since a brass knob for the locks of doors was made at Birmingham; the price at that time being 13s. 4d. per dozen. The same article is now manufactured, having the same weight of metal, and an equal, or, in fact, a slightly superior finish, at 1s. 9½d. per dozen. One circumstance which has produced this economy in the manufacture is, that the lathe on which these knobs are finished is now turned by a steam-engine; so that the workman, relieved from that labour, can make them twenty times as fast as he did formerly."

(916.) *Processes followed in the cutlery manufacture.* Forging table knives.—The forging of the different articles depends a great deal on their size, and the purposes for which they are intended; some being worked by one man, others by two or more. Table knives are commonly forged by two men, one of which is called the maker or foreman, the other the striker. The blade of the knife is first rudely formed and cut off, it is then welded to a rod of iron about half an inch square, in such a manner as to

Manufac-
tures.

leave as little of the iron of the blade exposed as possible; from this a sufficient quantity is taken to form the bolster and tang; the former being shaped by means of a die and swage, and the latter by the hammer. This part being finished the blade is heated a second time, and is finished single handed on the anvil by the foreman. It is then again heated red hot and plunged perpendicularly into water to harden it; it is afterwards tempered at a blue colour, and is then fit for the grinder.

Table
forks.

Table forks are formed from rods of steel, which are about three-eighths of an inch square. The tang and shank of the fork are first roughly formed, and then cut off, leaving at one end about one inch of the square part of the steel. This part is afterwards drawn out flat to about the length of the prongs. The flank and tang are then heated, and a proper form given to them by means of a die and swage. The prongs are afterwards formed at one blow by means of a stamp, a machine which is very similar to that used in driving piles, but it is worked by one man; it consists of a large anvil fixed in a block of stone, nearly on a level with the ground. To this anvil are attached two rods of iron of considerable thickness fixed twelve inches asunder, perpendicularly to the anvil, and diagonally to each other, which are fastened to the ceiling. The hammer or stamp, about 100 pounds in weight, having a groove on each side corresponding to the angles of the upright rods, is made to slide freely through its limited range, being conducted by its two iron supporters. A rope is attached to the hammer, which goes over a pulley on the floor of the room above, and comes down to the person who works the stamp; two corresponding dies are attached, one to the hammer, and the other to the anvil. That part of the fork intended to form the prongs is heated to a white heat and placed in the lower die, and the hammer containing the other die is made to fall upon it from the height of about seven or eight feet. This forms the prongs and the middle part of the fork, leaving a very thin substance of steel between each prong, which is afterwards cut out with an appropriate fly-press. The forks are now annealed by surrounding a large mass of them with hot coals, so that the whole shall become red hot. The fire is then allowed gradually to die out, and the forks to cool without being disturbed, which process is intended to soften, and by that means to prepare them for filing. The inside of the prongs are then filed, after which they are bent into their proper form and hardened, which is effected by heating them red hot and plunging them into cold water; they are then tempered by exposing them to the degree of heat at which grease inflames.

Penknives.

The smaller blades, such as those of penknives, are forged by a single hand with the hammer and the anvil simply. The hammer in this trade is generally light, not exceeding three pounds and a half, the breadth of the face or the striking part being about an inch. The principal anvil is about five inches by ten upon the face, and is provided with a groove, into which a smaller anvil is wedged, the latter being about two inches square upon the face. The blade of the knife is first drawn out at the end of the rod of steel, and as much more is cut off with it as is thought necessary to form the joint, it is then taken in a pair of tongs, and heated a second time to finish the joint part, and at the same time to form a temporary tang for the purpose of driving into a small handle used by the grinder; another heat is taken to give the blade a proper finish, and the small

recess called the nail hold, used in opening the knife, is made while it is still hot by means of a chisel, which is round on one side and flat on the other. Mechanical
Processes.

Penknives are hardened by heating the blade red hot, and dipping them in water up to the shoulder; they are then tempered by laying them side by side, with the back downwards, upon a flat iron plate laid upon the fire, where they are allowed to remain till they are of a brown or purple colour.

The blades of pocket knives, and all that come under the denomination of spring knives, are made in the same way. Razors are forged by two men, similarly to table knives. The forging of scissors is performed by a single hand, and there is perhaps no branch of cutlery in which more taste is displayed than in the manufacture of the finer sort of these articles. The steel employed is here of course of the choicest quality, it must possess hardness and uniformity of texture, in order that the polish may be perfect, and great tenacity when hot to allow of forming the bow or ring of scissors, which requires to be extended from a solid piece having a hole previously punched through it. It ought also to be very tenacious when cold, to allow of that delicacy of form and work more frequently seen in the better sort of these articles. After the two parts of the scissors are formed as nearly to the same size as the eye can judge, they are properly paired and fitted by another workman with a file; the blades are also roughly ground, and the two sides adjusted to each other; after which, being bound together with wire, they are hardened up to the bows, and then tempered to a purple heat. The remaining part of the work is performed at the grinding mill with the stone, the glazer, and polisher, as described below. Scissors.

It would be useless to enumerate more at length the various articles which fall under the general term cutlery; they are all made by hand, more or less, on the plans already described, and having received their form and been properly tempered according to their intended purposes, are handed over to undergo the next process of grinding and sometimes polishing.

(917.) *Grinding.*—This is an important part of the cutler's Art, and is almost the only part in which machinery is employed, which, however, is very simple, consisting only of a drum which is driven either by horses or steam power; on this are several straps passing over pulleys fixed on the same axles as the grindstones, thus giving to the latter a proper circular motion. Different kinds of stones, and of different thickness and diameters, are required in the various parts of the grinding process, but they are generally so arranged as to have nearly the same circumferential velocity, viz., about 600 or 700 feet per second; this is effected by adjusting the size of the pulley to the size of the drum and stone. The men employed in grinding sit astride on a seat called a horse, so high as to enable them to reach over it. The larger and broader stones are used for grinding saws, fenders, and other articles exposing large flat surfaces. Table knives are ground on a firmly indurated sandstone, as are also penknives, the blades of common scissors, &c., but the finer kind of scissors are ground on a harder sort of stone, but of a similar composition, with water. Forks and the shanks of scissors are ground on a dry stone termed the fork stone; it is a very sharp grit of a whitish colour, very similar in its nature to mill-stone burr. Grinding,
glazing,
and polish-
ing.

The glazer and polisher are driven by the same machinery as the grindstones, but are made to move

Manufac-
tures.

with different velocities, the circumferential velocity of that of the former sometimes amounting to 1500 feet per second. This cylinder consists of a circular piece of wood, or rather of many pieces, so as to present their ends to the circumference; it is mounted on an axle the same as the stones, and its surface is covered with leather or sometimes with pewter; in the latter case these are called caps, in others, the wooden face is made use of. Some of the leather-faced glazers, such as are used for forks, table knives, &c., are first coated with a solution of glue and then covered with emery. Others, for finer purposes, are turned very true, and then their surface is indented with a sharp-edged hammer, and the interstices are filled up with a compound of tallow and emery.

The polisher is similar to the leather-faced glazer, being a cylinder of wood covered with buff leather, and the surface of which is supplied from time to time, while in use, with crocus, sometimes termed co-leather of vitriol. The velocity of this tool is much less than that of the grindstone, seldom exceeding seventy or eighty feet per second.

For general articles the operation concludes with the glazer, it being only those of cast steel to which the operation last described, which gives the most perfect polish, is applied.

Grinding
and setting
fine instru-
ments.

The grinding of the finer edged instruments is performed upon a grindstone of close grit, called a Bilson grindstone, and only water is used in the process. The face of the instrument is afterwards made finer by subsequent grinding on mahogany cylinders with emery of different degrees of fineness, or on cylinders faced with hard pewter, and the last polish is given on a cylinder covered with buff leather, to which crocus, or the red oxide of iron is applied with water. In the last operation care is required not to heat the work too much, as this would let down the temper of its edge, which is, of course, very thin.

The next operation is the setting, which in fine instruments, such as razors, surgeons' lancets, &c., is a work requiring great skill and delicacy of operation. The grinding leaves a ragged edge, which it is the first effect of whetting to reduce so thin that it may be bent backwards and forwards; this is called the wire, and if the whetting proceeds too far it would break off in pieces without regularity, leaving a finer, though still imperfect edge, and tending to produce accident while lying on the face of the stone. This wire is, therefore, removed by striking the edge against the stone while inclined at a proper angle, first on one side and then on the other, leaving thereby an edge formed by the inclination of the two sides of about 100° ; the edge thus formed is generally pretty even, but is, of course, too thick, and must be again reduced by whetting; a finer wire is by this means produced which will require to be again taken off, if for want of skill or delicacy of hand the workman should have carried the operation too far. The edge, however, at length thus far obtained, is completed by one or two slight strokes with the edge slanting foremost, the blade forming an angle of about 28° ; a measure which Mr. Stodart recommends as the one which, from long practice, he found to be the best for surgical instruments, razors, and other fine cutting edges. The excellence and uniformity of a fine edge may be ascertained by its operation when slightly drawn along the surface of the skin or leather, or other soft substance. Lancets are tried by dropping the point on

a piece of thin soft leather, when, if the edge be such as is required, it will not only pass with facility, but there will not be the least striking noise. This kind of edge is obtained by one or two strokes on a green hone.

Mechanical
Processes.

Such are the means commonly employed in setting razors and surgeons' instruments; but the following, from the known skill of its author, we have little doubt is superior and deserving the attention of cutlers. It is given by Thomas Andrew Knight, Esq. in the *Journal of the Royal Institution for 1830*. Mr. Knight observes: "In the preparation of steel, and in the art of subsequently forming it into cutting instruments, British manufactures are, I believe, unrivalled, but in the art of giving the finest possible edge to their instruments when formed, I think that they have generally something to learn." The author then proceeds to describe his apparatus. This consists of a cylindrical bar of cast steel three inches long without a handle, and about one-third of an inch in diameter, rendered as smooth as can be made with sand paper or glass paper applied longitudinally, and the bar thus made perfectly hard. Before it is used it is well cleaned, but made brightly polished; its surface is then smeared over with a mixture of oil and charcoal of wheat straw, which contains a portion of fine silicious earth.

In setting a razor the practice recommended is to bring its edge into contact with the surface of the bar at a greater or less, but always at a very acute, angle, by raising the back of the razor proportionably to the strength of the intended edge, and moving it in a succession of small circles from heel to point and back again without any pressure beyond that of the weight of the blade till the edge is obtained, which, if the razor has been properly ground, will be effected in a few seconds, and it may be renewed again subsequently by repeating the process without grinding. The edge thus obtained is remarkably smooth, very different from the serrated edge obtained by the usual strap, but it is said to be by no means indolent, and is, therefore, considered to be admirably suited to the purposes of surgical instruments; but as the bar is not calculated to give the best point, (as for a lancet,) a plain surface is made about a quarter of an inch square by grinding away one side of the bar, and on this the point may be obtained.

(918.) Besides the finished polish which renders the choicest kind of cutlery articles so extremely beautiful, they are sometimes also variously ornamented. Scissors in particular are not unfrequently decorated with studs of gold, silver, or polished steel; these are added by means of a small tang inserted into small holes drilled in the scissors, or the parts are inlaid with circular pieces of gold which are polished with the scissors, and are afterwards ornamented on the surface by engraving; they are also ornamented by means of gilding, blueing, and etching. The gilding is performed in two ways: first, by dipping the finished article into muriate of gold in alcohol; the second with metallic gold laid on by means of heat; the latter, however, requires too great a heat and commonly leaves the scissors too soft, and the other is not sufficiently permanent.

Ornamen-
tal work.

Other steel articles are also elegantly ornamented with coats of arms and various devices, particularly razors and swordblades, which is generally effected by etching. To perform this the device in question is carefully put on the polished article with a varnish made by dissolving resin in oil of turpentine, and every other part is covered with the same varnish except that

Manufac-
tures.

which is to form the ground of the picture. The exposed part is then covered with dilute nitric acid, which is suffered to remain upon it till it is supposed to be sufficiently corroded. It is then rinsed in water to wash away the acid, and the varnish is removed by means of oil of turpentine; when the ground of the figure appears of a dead white, the device itself and all the other parts of the article display their original polish.

Handling.

(919.) *Handling.*—Most cutting instruments, with the exception of scissors, shears, and a few others, require to have some kind of handle attached to them, which in the larger and coarser articles are commonly of wood cut to the most convenient shape according to their intended use, and are fixed to the instrument or tool in various ways, too numerous to admit of, and too simple to require explanation; but in the finer articles the handling requires some delicacy and exhibits great taste and elegance, as in the better sort of table knives and forks, penknives, razors, and surgical instruments, where the material employed is gold, silver, pearl, tortoiseshell, ivory, horn, &c.

Of table
knives and
forks.

The handle is secured to the blade in two ways; *viz.*, either by having a hole drilled in the material forming the handle a little larger than the tang of the knife, in which the latter is fixed by a strong cement, or the tang of the knife being made flat and thin, the handle, consisting of two side pieces called scales, is rivetted through the tang on each side. The former, however, is by far the more general method.

Those handles formed of gold or silver are thin metallic shells which are pressed into dies in two halves cut to the proper figure, decorated according to the taste of the manufacturer; these are afterwards soldered together, filled with a composition of rosin and pulverized brickdust which becomes exceedingly hard, and serves to give great firmness to the shell of metal, and, at the same time, to secure the blade.

Ivory handles are cut by hand out of larger pieces of the material as nearly as may be to the required form, they are then drilled by a drill in a foot lathe, reduced to their proper form by a file, after which they are smoothed down by a sort of burnisher, cutting a little on its edge, rubbed over with its own sawdust, chalk, and a little oil; they are then fixed upon the knife. All these operations, although performed by hand, are done with expedition on account of the acquired dexterity of the workman.

Horn handles are brought to their figure by pressure, the horn being first softened in hot water and applied in proper sized pieces in hot dies with a little oil. The dies or moulds are sunk in the two parts of a pair of tongs resembling a bullet mould, but of larger dimensions; they are then taken to the pressing vice, as we have described in button-making, but it differs somewhat in shape from the former, the jaws or pressing part being below. The horn being thus formed, if its colour is not good, is dyed of different colours, as green, black, &c.

Penknives.

Penknives being made to shut require more ingenuity in affixing the handle. The ornamental parts of penknife handles are generally ivory, tortoiseshell, mother of pearl, or stag horn, and the manner of attaching these is so obvious to inspection as to require little explanation; but the scales to which they are attached, the spring, &c. involve some difficulty and very nice workmanship. This part is commonly made of iron, although brass and silver are occasionally used;

the spring is always formed of steel; this serves to keep the scales at their proper distance, and its elasticity exerted on the tang of the blade secures the knife in its situation whether shut or open. These parts, that is the inner and outer scales, and the spring being first formed, are put into the hands of a workman who is employed to complete the handling.

Mechanical
Processes.

The tools consist of a vice, a small hammer and anvil, files, burnishers, a breast-plate, drill bow and drills of various kinds, a glazer coated with emery and glue to polish the different parts, and a buff similar to the glazer but used with oil, fine sand, and rotten stone, which latter is used for polishing the surface of the outer scales. The glazer and buff are turned by the foot in a similar manner to that adopted by the common street grinder. The workman is also provided with a number of hardened steel plates about a twelfth of an inch in thickness, and in shape corresponding to the different patterns of the handles by which the spring and blade are first secured in their places. Each of the inner scales is secured to one of the above plates for the sake of drilling holes through them opposite to the holes in the plate, the scales are then fastened on each side of the plate by temporary pins, and the edges filed down to the plate which ensure the handles being of the exact pattern and size. The spring is next drilled and placed between the scales, being secured in its proper place by temporary pins, and is then filed level with the edges of the scales. A hole is now drilled through the tang of the blade, one of the pins is taken out, the spring thrown back to allow the blade to be inserted where it is at first secured by a temporary pin, the tang is then filed square to correspond with the bolster or thicker part of the inner scale and the spring.

Every part being thus properly fitted and adjusted to some other, the temporary pins are removed, and all the visible parts which could not be touched with the file while the pins were in are now made smooth, the spring is bent gently a little inwards in order to increase its elasticity, and is then hardened and afterwards tempered at the spring temper; the outer and all visible parts are now burnished. The outer scales having in like manner been fitted, the whole are finally rivetted together and the knife is complete, except the last process of polishing the outer scales, the joint, and bolster, the former by scraping and buffing, and the latter by a file and burnisher.

The handling of razors is a very simple operation; the materials of which they are formed are brought to shape either by cutting or pressure according to the nature of it. A piece of white metal, an alloy of lead and tin, is placed between the scales at one end to allow the razor to go between them when the razor is shut, the blade is then screwed into its place and the scales are fastened together by means of rivets of iron, brass, zinc, or silver, according to the quality of the finished article, which completes the work, the polish and finish having been given to the scales themselves previously to this last operation.

Razors.

Founding.

(920.) Foundry or Founding is the art of manufacturing articles in cast metal; but the former term is very commonly employed to designate the building or workshop in which the casting of metals is carried on.

Founding.

The art of casting in metal among the Ancients was

Manufac-
tures.

so limited in its extent, from the little progress that had been then made in Metallurgy, that it may almost be ranked among the modern inventions, at least as regards its application to the Mechanical Arts, in which iron is almost alone employed. In fact, we are indebted for the immense extent and advantages of the use of casting to the facilities afforded to mining by the invention of the steam-engine, without which it could never have attained its present extent and importance.

Construc-
tion of a
foundry.

In constructing a foundry an important circumstance to be attended to is, that the foundation be well drained of water, as any dampness in the moulds is likely to produce the most fatal explosions by the sudden expansion of the steam: for this reason the floors of foundries are very commonly supported on pillars, or are at all events raised considerably above the ground. The most complete of these buildings are furnished with two or more air or reverberating furnaces, and two or three cupolas or small blast furnaces, the former of which are employed when a large quantity of metal is required, and the latter, which consist simply of a cast-iron cylinder lined with bricks, when only small quantities of metal are wanted, or more particularly when a charge is required in great haste.

The floor of a foundry should be formed of loamy sand, about ten feet deep, for the convenience of burying large moulds beneath the surface, so that the metal may be conveyed to them from the furnace by channels formed in the sand.

Different
kinds of
casting.

Casting may be divided into three branches, *dry sand*, *moist or green sand*, and *loam*, the first and second of which are executed in a similar manner from a wooden pattern in flasks; the only distinction being that the former is used for the finer description of articles, or when a more complete surface is required, and the latter in the larger description of articles intended to be painted, or when the appearance is not a consideration of importance. The loam casting is generally employed in cylindrical or circular articles, and the figure of the mould is given by a board of the shape of the centre revolving upon an axle instead of a wooden pattern.

By far the larger proportion of articles is executed in sand from wooden patterns, the making of which forms the distinct trade of the pattern maker, who must be a good workman as a carpenter, and at the same time he ought to be perfectly acquainted with the means and methods employed by the founder, so as to arrange the different parts of the pattern that the impression of the figure may be executed in sand in the readiest manner, a task which, in cases of complicated shaped figures, calls for a considerable degree of ingenuity and thought.

Pl. lxxv.
Fig. 1.

Flask casting.—To illustrate the simple flask casting, we have represented in plate lxxv. fig. 1, the manner of casting the beam of a steam-engine, the figure of which is such that every part tapers each way from the middle line, and, consequently, if it is imbedded up to this line it may be withdrawn without disturbing the sand. A B C D are the flasks, which have four handles, *a, b, c, d*, to lift them up by, and points or pins, *e, f, g, h, &c.*, which fit into corresponding holes in the lower flask, that they may be correctly placed in the same position after being separated. The under flask is set upon a board and filled with sand well rammed down; the workman then takes the pattern and presses it into the sand until it is immersed up to the middle line; he then smooths the sand up to the sides of the pattern by a trowel which is

represented in fig. 2. He next sets the empty flask over the other, putting the pins into the holes of the lower one, and after sprinkling some burnt sand over the lower flask to prevent the sand in the two from uniting, he places two or more cylindrical pieces of wood in the position where it is intended the metal is to be introduced; he then fills the upper one and rams it well down with the tool, fig. 11. The pieces of wood are now removed, leaving openings from the surface down to the pattern, and little holes are made in all directions from the pattern by a small iron rod, to allow of the escape of the air and the expansion of the steam from the moisture when the hot metal is introduced. The upper flask is now lifted off by men, or a crane if the casting is of large dimensions, and the pattern lifted out by inserting at each end a little instrument shown in fig. 3, having a screw at one end by which it takes a hold of the pattern, and a handle at the other to lift by. The upper flask is now again carefully placed in its original position, and weights being placed upon it to keep them together the mould is in a proper state for casting.

Mechanical
Processes.
Fig. 2, 3.

Fig. 11.

Fig. 4 represents the manner of casting a cog wheel with eight arms, all of which are ribbed on both sides. The pattern is laid upon a board with the face shown in the figure upwards; an empty flask is laid inverted over the board and pattern which is filled with sand and well rammed. A plain board is then laid upon the flask and two men turn it over, bringing the pattern to the top as shown in fig. 5: the workman with the small trowel then digs all the sand out of the space A A between each arm, leaving it level with the top of the ribs *a b c d*, and into each of the spaces thus formed a piece of iron plate, fig. 6, cut of the exact figure, is inserted, which

Casting a
cog wheel
described.
Fig. 4, 5.

Fig. 6.

has an iron rod *a* projecting from the upper side, and two points *b d* at the under side, which are inserted into the sand between the arms, so that the edges *e f* touch the upper edge of the arms *a b* of the wheel. The spaces above these plates are then filled with sand and rammed down level with the rest of the sand in the flask, and burnt sand sprinkled over the lower flask to prevent the sand, which is now to be rammed in the upper flask, from adhering to that in the lower; the holes for the metal are next made through the top flask, and it is then taken off, the iron plates and the sand upon them are taken out by the ends of the iron rod *a*, and the sand round the pattern being slightly wetted to cause it to adhere more strongly together, the cogs of the wheel, which are fixed to it by means of dovetail, are withdrawn separately. The whole wheel is then lifted out and the iron plates are returned to their original position, which is determined by the holes made by the points *b d* in the sand. The hole H through the wheel which is to receive the shaft is made solid in the pattern, and a projection of the same size as the intended hole, termed a *print*, is fixed on, which forms a recess in the sand shown at *k*; into this is placed the core shown in fig. 7, made of well-tempered clay or wet loam, afterwards dried, which extends between the opening of the flask and, of course, produces a hole of the required shape in the casting. The upper flask is now again put on, and weights being added it is ready for casting.

Fig. 7

In casting large cog wheels, flasks are often wanted as large as twenty feet square, wooden bars are then required to keep the sand from falling out, which extend across the flask, and have long nails driven into them, these flasks are lifted by a crane.

In the variety of shapes which are executed in cast

Manufac-
tures.

iron, many occur which will not draw in two ways from any one intermediate line; and in such cases the pattern is required to be made in two or more pieces which are fitted very accurately together by pins, and a greater number of flasks is made use of. With the aid of these various contrivances there are few shapes which the ingenuity of the founder does not contrive to execute in sand casting; but the variety of combinations of those made are so great, that it is impossible, with the limited extent of this article, to convey to the reader any thing more than a general idea of the principles upon which they are executed.

Loam
casting

Pl. lxxv.
Fig. 8.

(921.) We have now to explain the third description of casting termed the loam casting, which is generally employed for circular and cylindrical vessels. In plate lxxv. fig. 8, is given the section of the mould for the cylinder of a steam-engine, which will sufficiently illustrate the manner of conducting this description of casting. A A is an iron frame, placed upon wheels for the purpose of being conveniently moved to any part of the foundry, in the centre of which is fixed a cylindrical tube or cylinder B B. C C is a ring of iron, with four ears of flanches for the purpose of lifting it, which is placed upon the frame as near as possible concentric with the cylindrical tube B B. Upon this ring a thickness of sand is first placed, and upon the sand a cylinder of brickwork is constructed, the interior diameter of which exceeds by a few inches the exterior diameter of the intended cylinder. A rod D D, provided with arms E E, is now placed in the cylindrical tube, and to these arms is bolted a mould of wood of the exact shape of the intended cylinder, which being revolved upon its centre D D forms upon the loam covering the internal surface of the brickwork the exact impression of the shape of the cylinder. The whole mould is then removed to an oven to be baked, and in the mean time, by a similar operation, a core of brickwork, covered with loam, is made of the size of the interior of the cylinder, the only difference in the operation being that the wooden pattern which gives the shape is placed on the exterior instead of the interior of the cylinder.

Fig. 9.

This has also to be rendered perfectly dry by baking. A pit is now dug in a convenient part of the foundry, of sufficient depth to contain the mould, into which it is lowered by a crane, and the apparatus shown in fig. 9 is used for slinging it to the crane. A B C D E is a wrought-iron cross, the arms of which are made sufficiently strong, or are strengthened by ties; on each of the four cross bars a ring with a hook is loosely fitted, from which ropes or chains extend to the flanches or ears before described in the bottom plate C C, and in this way, by sliding the hooks nearer or further from the cross, the mould may be made to hang vertically. When the mould and core are in this way let down into the pit and properly adjusted, the sand is thrown and rammed down about half the height; a flat cover of dried loam is then put on the top of the mould and core, and round pieces of wood are put into the holes which had before been made in the cover for pouring in the metal; the burying of the mould is then completed, and the sticks which keep open the holes for the metal being pulled out and small ditches made from the furnace to them, every thing is ready for casting.

Origin of
the Art.

(922.) *Casting statues.*—The casting of statues is one of the Arts which was practised and attained great perfection among the Ancients; but its first invention appears to have been at so remote a period that little is

known respecting it. The methods that were subsequently made use of by the Greeks and Romans appear also to be unknown; for notwithstanding the taste for statues which was at that time carried to such a pitch as to lead to the proverb that in Rome the people of brass were as numerous as the Roman people, it suddenly died away, no record of the process being preserved; and it was but little practised among the Moderns until the commencement of the XVIIth Century, since which time it has, however, again arrived at a considerable state of perfection.

Mechanical
Processes.

The first operation in the common method of casting statues is to form the inner mould or core, which is, in fact, a rude resemblance of the figure intended to be cast, but made smaller in all its dimensions; it is composed generally of potter's clay mixed with horse's dung and hair, or of plaster of Paris with fine brick-dust, and is strengthened with ribs of iron so as to enable it to maintain its figure. The rough core thus formed is covered with wax of such thickness that the dimensions of the figure may be in excess of that intended to be executed; and it is now in a fit state for the hand of the sculptor, who operates upon it in the same manner as if executing a statue in any other material.

Common
method of
casting
statues.

This part of the process is, however, sometimes different, inasmuch as the wax is formed on a model, and afterwards disposed and arranged on the core which is formed as the sculptor advances with the figure.

When by either of the above methods the core is completed, little tubes of wax are fixed perpendicularly to the surface from top to bottom, which serve both as jets for the conveyance of the metal to all parts of the work, and as vent-holes to give passage to the air, which would otherwise occasion great disorder when expanded by the heat of the fluid metal. This is now covered over with a coat or crust termed the shell, which being put on in a soft or semifluid state takes the impression of the different parts which it afterwards communicates to the metal. The material of which the shell is composed is varied accordingly as different layers or strata are applied; the first is a composition of clay and old white crucibles well ground and sifted and mixed up with water to the consistency of a colour fit for painting, which is applied with a pencil, laying it seven or eight times over and letting it dry in the intervals; for the second strata, horse's dung and earth are added to the composition; and the third, which is of considerable thickness, is composed simply of horse's dung and earth. The shell is now secured and strengthened by several bands or girts of iron wound round at about six inches distance from each other, and fastened at top to a circular ring, and at bottom to a grate upon which the statue is erected.

If the figure to be cast be of such dimensions that the mould in the state above described is too weighty to be removed to the furnace, the erection of it must be executed on the spot. A square hole is made in the ground near the furnace where the metal is to be melted, of sufficient dimensions to contain the mould, the sides of which are lined with freestone or brick. At the bottom of this is a hole of smaller dimensions covered over by the grate upon which the figure is erected, and contains a furnace to dry the mould and melt the wax. When the figure is complete, a moderate fire is lighted in the small furnace and the hole covered over with planks, which confines and equalizes the heat, and causes the wax to run swiftly down from all parts of the figure out of the pipes introduced for the purpose, at the

Manufactures,

foot of the mould, but which are carefully closed with earth as soon as all the wax is carried off.

The hole is now filled all round with bricks thrown in at random, and the fire in the furnace is increased until such time as the bricks and the mould become red hot, which ordinarily happens in twenty-four hours; it is then extinguished, and when every thing is cold again, the bricks are taken out and the space is filled up with earth well rammed in order to make the mould and firm steady.

Nothing now remains but to melt the metal and run it into the mould. The furnace resembles an oven in construction, and has three apertures, one to put in the wood, another for a vent, and a third to run the metal out at. From this aperture, which is kept closed while the metal is in fusion, a little tube or canal is laid by which the melted metal is conveyed to a large earthen basin situated over the mould; into this basin all the branches of the jets or casts which convey the metal to the different parts of the mould are inserted. All the jets are terminated or stopped with plugs which are kept close until sufficient metal is contained in the basin to supply the whole figure; they are then speedily removed by iron rods attached to them, and the melted metal rushes into and fills up all the cavities which had been previously occupied by the wax. The figure is now complete as far as the casting is concerned, but has still to pass again through the hands of the sculptor, who removes the jets and repairs any parts in which the casting is imperfect.

In the casting of statues of great dimensions, the quantity of metal employed forms a large item in the expense, and has led to the invention of methods of forming the moulds by which the thickness of metal can be more correctly adjusted to the required strength of the different parts than in the one above described, where such a thickness of wax is added as is necessary to complete the figure, and which of course is liable to be much greater than is required for absolute strength.

Valvasor's method of casting statues.

(923.) A method of casting statues very thin was invented by John Weichard Valvasor of Carniola, which with some slight variations has been applied of late years on the Continent with considerable success. The following is the author's description of the invention given in the sixteenth volume of the *Philosophical Transactions*.

"First, I form out of good clay that will endure the fire, and not crack either in drying or burning, any figure or statue desired; when this is well dried, I make all over the figure small holes of no great depth, but both in size and depth proportioned to the size of the statue; into these holes I put small pieces of metal, and with some of the same clay fix them firmly in the holes: the use of these bits of metal, marked in fig. 10, plate lxxv., *a a a*, &c., is to keep the core and mould from touching each other, or falling together when the wax runs out, and that they may remain constantly in the same fixed position. This done, I scrape away with some proper instrument as much of the clay in thickness as I design for the thickness of the statue; and laying it in a furnace the core or first clay statue is burned till it is red hot. When cold, the core is rubbed all over with a sort of earth or colour used by German potters to colour the joints of the tiles when they set stoves of tiles. This colour resembles black lead, and, being mixed with water, it is daubed all over the core because the metal is found to run freely upon it. This done, I lay upon the core as much yellow wax mixed

VOL. VIII.

with pitch or rosin as will make the thickness of the intended statue, which I form in the wax with all the exactness possible.

Mechanical Processes.

"Next, I put all over the surface of this statue of wax little pieces of wax termed the little channels *c c c*, all of them so contrived as to enter into the channels *d d d*, &c. This done, I cover the core and wax all over with the same sort of clay that will endure the fire without cracking, and thus the concave statue or mould is made. Upon this are laid the great channels *d d d*, both upright and transverse, formed likewise in wax and placed according to judgment, so as best to receive the ends of the little channels *c c*, &c., for the easier distribution of the metal.

"The great channels must all meet at the top of the statue so as to come out by one hole at *e*, where the metal is to be poured in; it is also necessary to have a channel or two to let out the air as the metal enters, as those marked *f f*; and there must be a hole or two left at the foot as *g g*, where the great channels and waxen statue join, and at which, when the mould is burned, the wax both of the statue and of the channels may run out. The great channels being thus placed, the mould must be again laid over with the same sort of clay, and when this mould is well dried, I heat the whole red hot.

"The mould being thus burned, I stop with the same clay the two holes *g g*, and then bury it in a pit, and proceed as is usual in casting of bells and the like; but care must be taken that the metal be very well melted. If it be a small statue not above a foot or two high whose mould may be managed in the hands, then I make a concave statue of wax of the thickness desired, and place upon it all the great and small channels as before, which done, I put it all together into a liquid substance, made of plaster and tile or brick-dust tempered with water.

"If the statue be intended very thin, I take copper, and when it is well melted, I mix with it a good quantity of zinc, the more the better the metal runs. I have sometimes for small and thin statues put in above a third part of zinc, and I have found by experience that this mineral makes the metal run more freely, and gives it a fair golden colour.

"The statue being cast, I take off the mould and cut off the channels, all which, both great and small, are filled with metal, which may be kept for further use; in these there is much more metal than in the whole statue, for if the statue be very thin, there must be more and larger channels; and so the cheaper the statue the more weighty the channels, and the more metal remains.

"To know the quantity of metal requisite for my intended work, I take a lump of the same mixture of wax and pitch with which I make the mould of my statue; and having weighed it I make a mould upon it, and cast in the same a lump of metal of the same size, which I weigh, and thereby compute the proportion of the weight of the metal and wax, and thus knowing the number of pounds of wax I use about the figure and channels, I can calculate nearly how much metal I should melt."

(924.) The method employed in casting the fine statue of Lord Hopetown, erected in Edinburgh in 1834, very much resembled that above described. In consequence of the unusually large dimensions of the figure, the sculptor, Mr. Campbell of Edinburgh, obtained permission of Government to have the use of the foundry in

Statue of Lord Hopetown.

Manufac-
tures.

the Royal Arsenal at Woolwich, where the author of the present Essay had frequent opportunities of inspecting it. The work was executed by Frenchmen, and the methods being entirely novel in this Country excited considerable interest; we trust, therefore, the following short description may not be uninteresting.

The figure is first made in plaster of Paris, of the exact shape and dimensions it is intended to be when completed in metal, and placed in an erect position on a firm platform. It is now covered all over by a shell, composed of a number of pieces fitted very correctly together, so that they may be removed and built up in another situation, forming in the interior a figure exactly resembling the original one in plaster. The work is commenced at the bottom, by covering with strong sand such part as is intended to form one block of the shell, to about an inch or an inch and a half in thickness, to which is added about one foot in thickness of plaster of Paris, which unites with the sand and forms one block; the remaining part of the figure is completed up to this height all round, in a similar manner by blocks, of which the number and arrangement must be such that they may be removed when the shell is complete without disturbing the sand. Another course is now commenced and completed in the same way, and the work is thus continued until the whole figure is completely surrounded by the shell. During the progress of the work, tubes are cast in with the plaster for the admission of the metal and for the escape of the air, as in the common method, and iron rings are let into the plaster for the convenience of raising and removing the blocks. When the shell is complete, it is taken to pieces and removed to the casting pit, where it is carefully rebuilt, and the interior filled up with the material to form the core. It is now a second time taken to pieces, leaving the core of the exact shape and dimensions of the original figure, from which is scraped off such a quantity of material as will give the necessary thickness of metal to each part of the figure. The shell is then again put together in its original position, and will, therefore, leave a space between the interior of it and the core exactly equal to the thickness of material which has been removed. Nothing now remains to be done but drying the mould and running off the metal, which operation is performed in the same way as in common figure casting.

This ingenious method of casting is the means of saving a great weight of metal, and from that cause consequently diminishes the expense; but it calls for so much greater degree of labour, that it is doubtful whether it will prove economical in this Country.

(925.) *Casting bells.*—The methods employed in casting bells does not differ materially from that which we have described as the common mode for statues, the thickness of metal being formed upon the core in wax, which is afterwards removed by melting.

A hole is first dug of a sufficient depth to contain the mould of the first bell, which must be wide enough to admit a free passage between the mould and walls of the hole, or between each mould and the walls if several bells are to be cast. At the centre of each intended mould a stake is driven very firmly into the ground which supports an iron peg, on which turns the pivot of the compasses used in the construction of the bell. The stake is encompassed at the lower end with solid brickwork termed the millstone, which serves as a foundation for the construction of the core. The core is constructed of bricks with intermediate courses of plain

earth and is solid except a small opening in the centre to contain coals for baking the core. The brickwork is rather less than the intended diameter of the core, and the remaining part is completed with a layer of cement made of earth and hog's dung, to which the exact interior shape of the bell is given by the compasses; it has, however, to be observed, that this cannot be done at one operation, as the shrinking of the core by baking materially alters the figure; the operation has in consequence to be repeated several times, the core being thoroughly dried between each operation.

The internal core being completed, a thickness equal to the intended thickness of the metal of the bell is removed from the compasses which are now of the shape of the interior of the shell or exterior of the bell. The material forming the interval between the core and the shell is composed in the part next the core of earth and hair, and the outer part of a mixture of wax and grease, which contains any coats of arms, inscriptions, &c., that may be intended to be executed on the bell.

Upon this surface the shell of the bell is constructed in different layers; the first of which is composed of the same earth sifted very fine and mixed with cow's hair, and a sufficient quantity of water to reduce it to a fluid state, which is poured over the surface of the wax and penetrates into all the sinuosities of the figures. When this layer is thoroughly dried, it is covered a second time with the same matter, but somewhat thicker. After this the wax is melted out, and the shell is completed by layers of earth mixed with cow's hair and hemp.

The ear of the bell requires a separate work, which is done during the drying of the several incrustations of the cement. It has seven rings, of which the seventh is called the bridge and unites the others, being a perpendicular support to strengthen the curves. It has an aperture at the top to admit a large iron peg bent at bottom, which is introduced into two holes in the beam, and fastened with two strong iron keys. Models are made of the rings with masses of beaten earth dried on the fire, which are gently pressed upon a layer of earth and cow's hair one half of its depth, and then taken out without breaking the mould. This operation is repeated for each of the twelve half moulds, two of which united form the hollows of six rings and the hollow of the bridge.

Upon the open space originally left for the coals are placed the rings which constitute the ear. The iron ring to support the clapper of the bell is first placed in this aperture, and the diameter of the thickness of the core is made up by a round lump of clay, which after baking is clapped upon the opening and secured with thin mortar, which binds the cover close to the core.

When every thing is in its proper place, the outside of the hollows of the rings are strengthened with mortar, in order to bind them with the bridge and keep them steady at the bottom, they are then left to dry that they may be removed without breaking. The whole shell is now raised from the core, the part composing the thickness of the metal is broken and removed, and the shell, previously smoked by burning straw under it to smooth the surface of the bell, is placed in its original position; an interval being of course left between the shell and the core equal to the space occupied by the earth, hair, and wax, into which is run the metal from a furnace, situated near the hole containing the mould, of a similar construction to that employed in casting statues.

Cannon
foundry.

The metal is however different, containing one-fifth part of tin, whereas that for statues is composed entirely of copper and zinc.

(926.) *Casting guns.*—The guns employed in the ordnance are of two kinds, *viz.*, iron and brass, the former metal being used in the larger description of guns, such as ship-mortars, ship and battery guns, carronades, &c., and the latter for the lighter pieces used in the field.

The iron guns which are supplied to Government by contract are cast in sand from a wooden pattern, in the common manner of sand casting; but in the brass guns, all of which are executed in the foundry of the Royal Arsenal at Woolwich, a totally different method is employed, which therefore requires a more particular description. The manner of preparing the mould will be understood by the following description. A wooden cylinder is made to revolve in bearings near its extremity, and is made of a taper figure to facilitate its being withdrawn; upon this cylinder the core or pattern for forming the mould is made in the following manner. A band of straw is first wound round from one end to the other, of such a thickness that the cylinder becomes nearly of the size of the intended gun; the band is now covered over with a composition of loam and dung, and a pattern formed in wood edged with iron, of the exact shape of the intended gun, is pressed against it, while a workman with the aid of handles turns the round core, and causes it to take the impression of the shape of the gun. The core is now dried by means of a charcoal fire lighted in the pit, and a fresh quantity of the composition is added to such parts as are found imperfect, and the pattern or mould is again applied. It is then again dried, and if any parts are found imperfect, or if the dimensions do not agree with the drawing given by the superintendent, the operation must be repeated as many times as may be necessary to render it quite correct.

By this process all the cylindrical parts of the gun, from the breech to the muzzle, are formed, as also a cylindrical part extending beyond the muzzle, the object of which is to consolidate the metal of the gun and render it of a more equal density; this part, after the gun is cast, is of course removed. The trunnions, dolphins, and such parts as are not cylindrical, have now to be added; the trunnions are made of the same composition of loam, &c., and are fastened to the gun by means of iron pins; but the dolphins and all other ornamental parts are formed in wax, which is afterwards melted away. The core being thus complete is covered over with loam mixed with water, at first in a fluid state, and in thin layers, and afterwards with thicker layers of less fluid matter, until it is covered with a thickness of material equal to the projection of the trunnions above the gun, so that they are on a level with the exterior surface of the mould. The mould when dry is secured with iron hoops, and the interior core is removed by blows on the smaller end of the taper cylinder, which soon loosens it and permits its being withdrawn; the workman now seizes the end of the straw band and pulls it gently out, and by that means so completely breaks and destroys the loam composition, that it can be readily removed without any difficulty, leaving a perfect impression of the cylindrical parts of the gun in the interior of the mould; heat is then applied, which melts out the wax used for the ornamental parts, and the mould of that part of the gun extending from the breech to the muzzle is complete and ready for casting.

The mould for the breech of the gun, which is made

in a separate piece, is executed in a similar manner in loam, by revolving it in bearings against a pattern of the required figure. The exterior of the mould is in this case also turned to a particular figure to fit a cast-iron step, which is firmly bedded at the bottom of the hole in which the gun is to be cast, and which serves as a foundation for the mould. When the mould for the breech of the gun is prepared as above, and dried ready for casting, it is placed in its step in the hole in front of the furnace, and the earth filled in all round it to make it quite firm and steady; the mould of the body of the gun is now placed in its position exactly over it, and the ground is filled up to the top, when nothing further remains to be done but running the metal from the furnace, which being of the ordinary construction requires no particular description.

The alloy for brass guns is made at two operations, as follows:

The tin is first converted into what is called hard metal or alloy, 75 parts copper and 25 parts tin, for the purpose of preventing its escape in vapour, which would take place to some extent if thrown into the furnace alone.

The copper is then melted and brought to the proper state for casting, at which time the above alloy is introduced and the whole well stirred together.

Gun metal is composed of 12 pounds tin to 112 pounds copper, or 46 pounds alloy, as above, to 76 pounds copper.

(927.) *Casting lead pipes.*—Until of late years, the greater portion of the leaden pipes used in water-works was made of sheet lead wrapped round an iron or wooden core, and the joint soldered up; but the expense of this method being considerable, and the pipes thus made being extremely liable to burst at the joint, suggested the idea of casting them, by which the labour of previously casting and laminating the lead into sheets would be spared, and also the uncertainty of the soldered joints. Such pipes are cast in an iron mould made in two halves, forming when put together a hollow cylinder of the size of the intended pipe; a core or iron rod is adapted to this mould, which is secured by screws or wedges, so that it exactly occupies the centre of the hollow mould, leaving therefore an equal space all round, and a spout or entry for the admission of the melted lead is made by a corresponding notch cut in each half of the mould, and at another place a similar vent for the escape of the air. This mould is fixed down upon a long bench, and a rack moved by toothed wheels and pinions is fitted at one end of it, in a line with the centre of the mould, which, by a hook inserted into an eye at the end of the core of the mould, affords the means of drawing out the core when the pipe is cast. The halves of the mould are then separated and the pipe is moved along, so that only an inch or two of its end remains in the mould, the halves of which are again fastened together with the core between them, and its end entered an inch or two into the first piece of pipe. The mould is now filled with melted lead, the heat of which fuses and unites it with the end of the first piece so as to double its length, and the core again drawn out is ready for adding another piece. In this way any length of pipes may be cast, but the metal is liable to have air-bubbles in it, which produce holes where the metal is thin; besides which the joinings of the different lengths are not always perfectly sound.

Another method, therefore, which is now very generally adopted, is to cast the lead in an iron mould, upon a cylindrical rod of the size of the bore of the intended pipe,

Casting
lead pipes

Manufac-
tures.

the space left for the metal being three or four times the thickness of the intended pipe, and in short lengths, which are then drawn through holes in pieces of steel in the manner of wiredrawing till the metal is reduced to the intended thickness and length. Another method is to reduce the pipe by repeatedly passing it through the two rollers of a flattening mill, in each of which a number of semicircular grooves are formed all round, so that the two rollers when united have circular cavities between them, which gradually diminish in diameter from one end of the rollers to the other. The pipe is first rolled between the largest of these cavities, then in a smaller, and so on to the last, which extends it to its proper length and diminishes its substance to the thickness required, at the same time by condensing the metal hardens it, and makes it very strong. Mr. John Wilkinson of Brosely, the celebrated iron manufacturer, took out a Patent in 1790 for the above method which he practised on a very extensive scale; he appears, however, not to have been the original inventor, the same thing having been proposed in 1728 by Mr. Fayolle. See *Machines approuvées par l'Académie Royale*, vol. v. p. 50. Since the expiration of this Patent, many manufactories of this article have been established, some employing rollers, and others the draw-bench for extending the pipes.

Apparatus
for drawing
lead pipes.
Pl. lxvi.
Fig. 7, 8.

(928.) *Apparatus for drawing lead pipes.*—In plate lxvi., fig. 7, 8, we have given sections of the mould for casting the pipes, with an elevation of the apparatus connected with it.

a a is the bench which is supported on legs in an inclined position, and *b b* are the two halves of the mould fitted into each other with double rebates (as shown in the section, fig. 8) that they may come together correctly, and *d d* are screws fitted through pieces of iron attached to the bench, by which they are secured in their position when thus united; the halves of the mould are made flat at each end on the under side, and rest upon the iron plate connecting the two pieces *e e*. *f* is the core which is held in its position by collars at each end of the mould, and *g h i* is the rack and wheelwork for drawing it out. The intention of the inclined position of the mould is that the metal which runs in at the lower end by the entry *c* may expel the air as it rises at a vent in the upper extremity, in the position marked *v* in the drawing, by which the danger of air-bubbles is entirely avoided. Attention must be paid that the interior surface of the mould is bored out truly cylindrical as well as to the core being turned in a lathe, that they may be certain, when united, to leave an equal space all round; a circumstance which is essential to forming a good pipe, as the succeeding process of drawing will tend to make an error of this kind worse. The core *f* has a neck or smaller part at the end *d*, as seen in fig. 8, and the treble or core *a g*, fig. 9, upon which the pipe is to be drawn, is of the same size and has a smaller neck, so that the pipe when put upon it fits in every part, and the shoulder of the neck prevents it being drawn through the pipe in the direction from *g* to *a*, being inserted in the opposite direction. Beyond the neck the treble has a notch cut in each side at *g*, which is seized by a sort of claw of the machine employed for drawing the tube, an elevation of which is shown in fig. 10 of the plate. The framework of the machine is composed of two strong timbers *A A*, which are firmly secured at one end to uprights *B B*, and at the other to a cross beam *C*. *D* is a cog wheel put in motion by a water wheel or steam-engine, on

Fig. 10.

the shaft of which is a drum or roller *E*, which is free to revolve on the shaft, but can be put in connection with it when required by the handles and levers *F F*. The drum *E* has a pair of spiral grooves formed on its circumference for the reception of two chains, the ends of which are hooked to a carriage *c* running upon two wheels, and provided in the hinder part with a fork or double claw to engage the notches at the end of the treble *T*. *C* is a cast-iron frame securely bolted down to the cross beam *C*, which has a notch in the upright side nearest the roller, to allow the treble and pipe to pass through, but at the same time forms a lodgement for the steel plate through which the pipe is to be drawn. The workmen are provided with a great number of these plates which are termed whistles, one of which is shown in fig. 11. The holes in the whistles are made rounding at each side as shown in the section, fig. 12, to facilitate the exit and entry of the pipe, and diminish very gradually from the size of the rough-cast pipe to that to which it is intended to be reduced.

The process of drawing is as follows: the lead pipe being fitted upon the treble is laid upon the rollers in the bench, and the end of the treble being put through the largest of the set of whistles, its end is hooked into the claws in the carriage *c*, and the whistle lodged against the cheeks of the frame *G*. The drum is now put in gear with the wheelwork by the levers *F F*, which winds up the double chains and draws the pipe through the whistle, by which it diminishes its size and lengthens it out. When the pipe is drawn completely through, the roller is cast off by returning the levers *F F*, the treble is unhooked from the carriage and pushed back into its former position, and a smaller whistle being put on, the pipe is drawn through as before, and the operation is in this way repeated using smaller whistles each time, until the pipe is rendered of the required length and thickness. Sometimes the pipe is drawn through as many as twelve whistles, in which case, for the second and eleventh time a whistle is employed, of the section shown in fig. 13, which having a sharp edge, cuts off a shaving from the surface of the lead making it perfectly smooth and true, and causes it also to pass more easily through the succeeding whistles.

Lead pipes are by these processes drawn out to ten or twelve feet length, three of which are united into one by an operation termed *burning*. An iron core is put through one pipe and entered a few inches in the other, and a small iron mould is put together in two halves over the ends of the two pipes which are brought in contact, the mould exactly fitting both. Melted lead is now poured into the mould which runs out again at a hole in the bottom, until it is supposed the heat of the lead has fused the ends of both the pipes, when the hole in the bottom is stopped by a slider adapted to the purpose, and the mould remains full and forms when cold a union of the pipes, which is perfectly good if the pipe remains straight, but is liable to leak if a bend is made at one of them.

In the year 1804 a Patent was granted to Mr. Alderson, for a mode of manufacturing lead pipes lined with tin, for the conveyance of beer, water, or other fluids, which were in danger of receiving an injurious taint from the corrosion of the lead. The method consisted in first casting a lead pipe in the manner above described, withdrawing the core and throwing into the pipe a small quantity of powdered rosin, and then inserting a core rather smaller in diameter than the first.

Alderson's
Patent.

Fig. 10, 11,
12, 13.

Manufactures.

The pipe was then placed in a vertical position, and the core being placed concentric with it so that an equal space was left all round, melted tin was poured in, which as it rose in the pipe melted the rosin which acted as a flux to unite the two metals. This pipe was then lengthened out by rolling or drawing in the manner above described.

Bramah's Patent.

Mr. Bramah also invented a very ingenious mode of manufacturing lead pipes, for which he took out a Patent, which consisted in pumping or forcing the metal in a fluid state into the moulds. A boiler or kettle is fitted up over a fire-grate with flues for the fusion of the metal, in the centre of which a force-pump is fixed, provided with a suction valve to draw in the melted lead from the boiler; the forcing pipe proceeded through the side of the boiler and conducted the lead to the mould, which consisted of a tube bored perfectly smooth and cylindrical, its interior diameter being equal to the outside of the pipe intended to be made. The end of the mould nearest the boiler was expanded in a conical mouth of larger diameter than the mould, and across this a bar was fixed to support the mandril of a diameter equal to the bore of the intended pipe, which was situated exactly in the centre of the mould, leaving an equal space all round, and was made slightly conical. The mould was situated in one of the flues surrounding the boiler that the lead might be preserved in a fluid state to within a short distance of the end, which was immersed in a cistern of hot water; by this means, when the force-pump was in action, the lead remained melted until it arrived at the extremity, which it quitted in the form of the manufactured pipe, and could thus be made of any length required. This method, although very ingenious, we believe, produced pipes more liable to fracture than the other above described, and has not for that reason been much adopted.

Type founding. Pl. lxvi. Fig. 1, 2, 3.

(929.) *Casting letters or types.*—In plate lxvi., fig. 1, 2, is given a perspective view of the upper and lower half of a mould employed for this purpose, which, when united, (as shown by the dotted lines in fig. 2,) form a space or mould to receive the metal, on which the letter is to be formed. A A is termed the carriage of the mould, and corresponds with the part B in the opposite half, and is fitted to it by the projections and corresponding recesses C C, G G, termed the male and female gauges. The upper part of the mould E is termed the *pallet*, and inclines each way from the body so that when the two halves are united a space is left resembling the figure of the frustum of a pyramid. The pallets and body are cast in one piece, and are attached by the plate *a a* to a piece of wood *b b*, which serves to give bulk to the mould and render it more convenient to handle, and at the same time, from its being a bad conductor of heat, prevents the heat, which the mould acquires after being used for some time, from incommoding the workman. The remaining parts of the mould, *viz.*, *f*, which is termed the *nick*, F I the register, (see also fig. B,) *g g* the stool, and *h h* the *spring* or *bow*, (shown broken in the figure,) will be better understood when we describe the operation of casting. The part by which the impression of the letter is given, termed the matrix, is shown at H in the figure, and separately in fig. 3. It is composed of brass or copper, and is about one inch and a half long, and of a thickness in proportion to the size of the letter it is to contain, which is impressed upon it by means of a punch.

The metal of which the letters are made is generally prepared in large quantities and cast in bars of about

twenty pounds weight, which are delivered out to the workmen as they may be required. The furnace for the purpose, which is built under cover, is provided with a revolving vent in order that an equal degree of heat may be given to every part of the vessel in which the metal is melted, which is of cast iron, and contains, when full, several hundred weight of metal. When the fire is heated, the bars of lead are let down gently into the pot, and the fusion is promoted by adding a quantity of pitch and tallow; the flame thus produced is drawn very fiercely into a flue situated about a foot beyond the furthest lid of the pot, which makes it act very powerfully in melting the lead, and at the same time assists in conveying away the fumes, &c. from the workman to whom this laborious part of the business is committed. When the lead is thoroughly melted, a due proportion of the regulus of antimony and other ingredients are put in, and more tallow is inflamed to make the whole incorporate sooner. The workman now, having mixed the contents of the pot very thoroughly by stirring them with an iron ladle, draws off the metal into small troughs of cast iron, which are ranged to the number of eighty or a hundred upon a level platform faced with stone.

In the course of the day fifteen hundred weight of metal can be prepared in this manner; and the operation is continued for as many days as are necessary to prepare a stock of metal of all the various degrees of hardness.

Before the founder commences his work, he melts a quantity of the metal, prepared as above, in a furnace of smaller dimensions, and provides himself with a ladle which will hold a quantity proportional to the size of the type intended to be cast. He then attaches a thin piece of leather to the matrix, fig. 3, by means of a string wound round the little groove *ee*, and after putting the two halves of the mould together, and placing the matrix in the matrix cheek, he attaches the other end of the leather to the wood of the upper half mould by rosin, so that after they are separated to deposit the type, and reconnected, the matrix will assume its correct position by simply pressing it into the cheek.

Fig. 3.

He now takes the under half of the mould in his left hand, embracing the wood part between his thumb and three fingers, and places the upper half of the mould upon it so that the pin gauges may fall into the recess gauges; he then clasps his left-hand thumb over the upper half of the mould and quickly catches hold of the bow or string at the top of it with his right-hand fingers which he presses against a notch at the back of the matrix; at the same time with his hinder fingers he draws the under half of the mould towards the ball of his thumb that both the registers of the mould may press against both sides of the matrix, while his thumb and fingers press both halves of the mould close together.

He now takes the ladle, which is placed full of metal at the hole of the furnace, in his right hand, and applying the jet of it to the mouth of the mould, pours in the melted metal, at the same moment he tilts the mould forwards, or, as it is technically termed, receives the metal with a strong shake, which causes it to pass more rapidly without cooling to the face of the matrix, and consequently to take a more perfect impression. The workman then separates the mould by placing his right-hand thumb on one end of the wood, and his two middle fingers on the other, and throws the letter upon a sheet of paper laid for that purpose on the bench, and is then ready to cast another letter as before.

Mechanical Processes.

Manufac-
tures.

When the foundrymen have got a certain number of types boys come and break off the jets, fig. A, which they throw into the pots and carry the type in parcels to other boys who polish the broad sides upon smooth, flat stones. This is a very dexterous operation and is a remarkable instance of what may be effected by the power of habit and long practice; for these boys in turning up the other side of the type do it so quickly by a mere touch of the fingers of the left hand, as not to require the least perceptible intermission in the motion of the right hand upon the stone. The types thus finely smoothed and flattened on the broad sides are next carried to a third set of boys who sit at a square table, two on each side, and who arrange them on long rules or sticks fitted with a projection to prevent them from sliding off, which are placed upon a set of wooden pins fixed into the wall in order to undergo the finishing operation.

This requires a workman of considerable experience and skill: he takes one of the rules and, with a peculiar address, slides the whole column of types upon an instrument termed the dressing-stick, which is made of well-seasoned mahogany, and furnished with two end pieces of steel, one of which is movable and can be made to approach the other by means of a long screw-pin inserted in the end of the stick. The types are placed on this instrument with their faces next the back or projection, and after being adjusted so as to stand even, they are made fast by the screw before described; the whole, if requisite accuracy is given to the moulds, assuming the appearance of one solid, contiguous plate of metal. In this position the workman smooths the narrow edges which could not be done on the stone, by scraping the surface of the column with a thick edged but sharp razor, until the whole becomes one plane, and he afterwards turns them over and completes the other edges in the same manner. The next operation is that of bearding or barbing, which is effected by running a plane, faced with steel, along the shoulder of the body next the face, which takes more or less off the corner as occasion may require; and this being completed nothing now remains to be done but the grooving, which is a very material operation, as the superfluous metal of the jets which still remains on the types would make them bear very unequally against the paper while under the printing press, and effectually mar the impression. The grooving operation consists in removing this superfluous metal, and in making a groove that the bearing of every type may be regulated by the shoulders imparted to them from the mould; this is done in the following manner. The types being screwed up in the stick as before mentioned with the jet end outermost, and projecting beyond the wood about an eighth of an inch, the stick is put into an open press, and every thing being made fast by a long wedge which bears upon a slip of wood lying along the length of the types, a plough or plane, made of polished iron, is applied, which is so constructed as to embrace the projecting part of the types between its sides, and which in one or two applications removes all the superfluous metal of the jet, and, by means of a steel cutter bearing between the shoulders, forms a similar groove on the head of each of the types. The types being now finished are removed from the press and examined by turning the faces to the light to perceive any imperfect or damaged letters, which being removed the remainder are complete and ready for sale.

(930.) *Casting stereotype.*—This method of printing by casting in an impression taken from the movable type in plaster of Paris, although a modern invention, has arrived at a great state of perfection, and is now becoming adopted in all Works for which there is a large demand, or those of which the demand is continued long after the first publication. Mechanical Processes.
Stereotype founding.

The introduction, progress, and the more particular application of this important invention are given under PRINTING; we propose at present simply to describe the processes of casting as performed in the most improved printing-offices of London.

After the type has been set up, as in the usual manner of printing, and carefully examined and corrected, a single page is placed in the lower part of a moulding frame A A, represented in plate lxvi., fig. 4, and wedged up tight by wedges *a a a*. The upper part of the frame B B, which is somewhat larger than the page, is placed over the lower frame, resting upon the wooden wedges, and determines the dimensions of the mould, the plaster being filled into this up to the level of the rim. After the upper frame is adjusted in its position, the types are rubbed with an oily composition to prevent the plaster of Paris adhering to the face of the type which would of course render the mould imperfect; but to prevent this effect entirely, considerable care is required not only in covering the type in every part with this oily substance, but in the preparation of the plaster and in the separation of it from the page.

The plaster when first applied is in a very fluid state, and is poured very evenly over the surface; more is then added until the frame is filled up level with the rim, and the plaster having by this time become much thicker, in a very short time the whole is perfectly set and may be removed from the page. The workman then examines it, and if found to be perfect, it is trimmed round the edges with a knife, and several notches being cut in the margin to allow the metal to enter the mould, it is fit for baking; a process which also requires a great deal of care and experience, as any irregularity of the heat of the oven would cause the moulds to warp.

In fig. 5 of plate lxvi. is given a perspective view of the casting box, in which the metal impression from the plaster mould is taken in the following manner. The mould, when sufficiently baked, is removed from the oven and placed upon a movable plate of cast iron, situated at the bottom of the pot (termed the footing plate) with its face downwards, and upon the back of the mould rests the cover of the casting box, the inside face of which, as well as that of the floating plate, are made perfectly accurate. The cover being held firmly down by means of a screw *a* and shackles *b b*, the whole is lowered by a crane into a boiler or pot containing the melted metal, which enters through the openings *c c c c*, at the four corners of the box, and insinuates itself between the floating plate and the mould, forcing against the under surface of the mould with a degree of pressure which causes it to enter every sinuosity.

After having remained immersed for about ten minutes, it is steadily lifted out by the crane and swung to a cooling trough by which the under side of the box is exposed to water; and when thus cooled the workman proceeds to remove the mould, which with the new formed type and floating plate forms one congealed mass. After the superfluous metal and plaster are removed the stereotype comes out bright and well formed, but is yet imperfect, as the proper thickness

Manufactures.

cannot be determined by the mould alone, but each plate has afterwards to be reduced to an equal thickness by a lathe in which the plate revolves against a cutting tool, which moves along the face by means of screws.

The edges of the plate are then trimmed, and it passes into the hands of a workman, termed the *picker*, to undergo the finishing operation, which consists in minutely examining every part of the plate and removing the small globules of metal which occasionally fill up such letters as the *a* or *e*, inserting new letters if any should be broken, or, which is a more delicate operation, removing with a graver any impurities which may fill up the lines of wood-cuts, which are executed in the same manner as the types and form part of the plate.

Gold Beating.

Gold beating.

(931.) The origin of this Art is not known, but it seems to be of some antiquity. It is mentioned by Homer, but from a description by Pliny of Roman gilding, the thinness of the leaf bore no comparison with that of the modern gold beater, one ounce of gold forming only 750 leaves four fingers square, whereas the thinnest gold leaf of French manufacture does not exceed the 480,000th part of an inch, that of the English being about the 300,000th part. This refinement in the Art is, therefore, comparatively modern, and is very interesting, not on account of any machinery or any extraordinary skill which it calls into action, but for the extreme point of reduction thus obtained, and the practical illustration it affords of the great divisibility of matter and the ductility of the precious metals, particularly of gold; for although silver leaf and even brass leaf are obtained, the thickness is not reduced to the same extent as in the case of gold.

Preparation of the metal.

The gold in preparation for beating is melted in a black-lead pot or crucible with borax in a wind furnace, and as soon as it is in perfect fusion it is poured into an iron ingot mould six or eight inches long, three-quarters of an inch wide, previously greased and heated so as to make the grease run and smoke, but not so as to flame. When the gold is fixed and solid it is made red hot to burn off the unctuous matter, and then forged into a long plate, which is further extended by passing it between polished steel rollers till it becomes no thicker than a ribbon or a sheet of paper. The plate or ribbon, as it is called, is carefully divided by compasses, and cut by shears into equal square pieces; each of these pieces are again worked by hammer on the anvil till it is one inch square, and are then annealed to correct the rigidity acquired by the forging and flattening mill, each piece weighing about six grains, and therefore in this state being about $\frac{1}{750}$ th of an inch in thickness, 150 of them weighing two ounces, the quantity commonly operated on at a time.

These are now to be extended by beating; and to effect this it is necessary to interpose some smooth body between them and the hammer for the purpose of softening the blow and defending the gold from its immediate action, as also to place between every two of the plates some intermediate substance, which, while it prevents their uniting together, may suffer them to extend freely; these objects are attained by means of certain animal membranes. These are of three kinds, and used for different purposes: first, the outside cover is commonly parchment made of sheep skin; secondly, for interlaying with the gold in the early state of the

process, they use fine vellum made of calf's skin; and thirdly, for the latter part of the operation, the fine skin of ox-gut slit open and prepared for this purpose only, and hence called gold beater's skin.

Mechanical Processes.

(932.) *Process of beating.*—The bed on which the beating takes place is a smooth block of black marble weighing from 300 to 600 weight, about nine inches square on the upper surface, fitted into a wooden frame two feet square, so that the frame and marble surface are one level, the back and both sides are furnished with a high ledge, and the front, which is open, has a leather flap fastened to it which the gold beater uses as an apron for preserving the fragments of the gold which may fall off. The only tools are three hammers having round and somewhat convex faces: the first or heaviest, called the *cutch* hammer, is about four inches in diameter, and weighs about fifteen pounds; the second is called the *shoddering* hammer, weighs about twelve pounds, having the same diameter; and the third, still nearly of the same diameter, weighs about ten pounds. The square pieces of gold plate (150 in number) above mentioned are interlaid with leaves of vellum about three or four inches square, one leaf being laid between every two, and about twenty more leaves are laid on the outsides, over these is drawn a parchment case open at both ends, and over this another in a contrary direction, so that the vellum and plates of gold are kept tight and close. The whole is then beaten with the heaviest of the three hammers till the gold is extended to the breadth of the vellum, the pieces are then taken out of this case, are each cut in four with a steel knife, and the 600 pieces thus produced are interlaid in the same manner with pieces of the ox-gut skin. The beating is then repeated with a lighter hammer till the gold has acquired the extent of the skin, when they are again divided into four pieces each by a piece of cane brought to an edge. The whole number of leaves is then divided into four parcels which are interlaid as before, and beaten separately till they are stretched, for the third time, to the breadth of the skins. After this last beating the leaves are taken up by the end of a cane instrument, and being thrown flat on a leathern cushion are cut to a size one by one with a square frame of cane made to a proper edge, or a frame of wood edged with cane. They are then placed in small books between twenty-five leaves which are well smoothed and rubbed over with red bole to prevent sticking. In this state they are sent into the market.

Description of apparatus.

Process of beating.

It may be proper here to observe, that the gold used for this purpose is never pure, because pure gold is too ductile to be worked between the gold beater's skin; the finest gold for the purpose has three grains of alloy in the ounce, and the coarsest twelve grains, but in general the alloy is about six grains to the ounce or one-eighth part. The alloy is silver or copper or both, and the colour produced is of various tints accordingly. Two ounces two pennyweights of gold are delivered by the master to the workman who, if skilful, will return 2000 leaves or eighty books, together with one ounce six pennyweights of cuttings.

The leaves being 3.3 inches square on the side, it may be shown that each leaf averages $\frac{1}{25000}$ th part of an inch in thickness; but the French, who carry the process further than the English, are said to reduce the thickness to the $\frac{1}{40000}$ th part of an inch.

The process of gold beating is very much influenced by the weather: in wet seasons the skins become damp, which renders the process tedious; the best workings

Manufac-
tures.

are in fine weather and with new skins, the latter losing their smoothness after being once or twice used, but will last through six or eight beatings.

We have seen that the gold beater cannot mix a superabundant quantity of alloy with the gold without destroying its ductility, but a means has been devised of producing what is called party gold leaf, the basis of which is silver, and which has only a superficial coat of gold on one side. This is done by placing a thick leaf of silver and a much thinner one of gold upon each other, which being heated and pressed together unite and cohere, and this being submitted to a process in every respect similar to the one above described, the gold, though in quantity only about one-fourth of that of the silver, is found every where to cover it, the extension of the latter keeping pace with that of the former.

Gold Wire Drawing.

Gold wire
drawing.

(933.) What is called gold wire is, in fact, only gilt wire, at least there is very little actual gold wire made, and that only for one purpose, filigree work. The common gold wire is made by covering a silver rod of about an inch thick, two feet in length, and weighing about twenty pounds, with a coating of gold, and then reducing it into wire by drawing. The purity of the gold employed for this purpose is a matter of great importance, as on this depends the beauty and durability of colour when wrought into laces, brocades, &c. The fineness of the silver is of less consequence, it is indeed better when alloyed, being too soft in its natural state for this work. The gold is employed in thick leaves made for the purpose, which are applied all over the silver rod and pressed down hard upon it with a burnisher, more or less of the gold leaves being laid over each other according to the intended quality of the wire. The smallest quantity of gold allowed is 100 grains to a pound of silver, and the largest quantity seldom exceeds 140 grains.

First pro-
cess.

The beginning of the process as well as the preparation of the material is performed by the refiner who uses pieces of hardened steel with a piece of tough iron welded on the back to prevent the steel from breaking; in this back part holes are made considerably larger than the corresponding ones in the steel and of a conical shape, partly that the rod may not be scratched against the outer edge, and partly for receiving some bee's wax which allows the rod to pass more freely, and preserves the gold from being rubbed off. This end being properly secured in a strong frame and the end of the bolt reduced so as to pass through the hole, this end of the bolt is seized by a pair of strong pincers whose jaws are cut somewhat like a file to prevent the rod from slipping out by the violence necessary for drawing the bolt through, the branches or handles of the instrument are bent upwards and a loop put over the curvature, so that the force which draws them horizontally serves at the same time to press them together. A sufficient power being now employed the bar is drawn through, reduced in diameter and extended in length; the same process is repeated with smaller holes till the original bar has been reduced to about one-fourth or one-fifth of an inch in diameter, in which state it is sent from the refiner to the wiredrawer.

Drawing
plates.

In reducing the coil of wire from the size above stated, a particular kind of plate is employed principally received from France; it is a metallic mass, its principal

part being iron. There are two sorts of these plates, one of considerable thickness for the wire in its largest state, the other only about half as thick for the smaller wire where less force is required. These plates, although in some degree brittle, have sufficient toughness to admit of the holes being beaten up or contracted by a few blows with a hammer, so that when any of them have been widened by the wire passing through they may be reduced again, the hole after each beating being opened by a long slender instrument made of the finest steel, one end of which, to the length of about five inches, is round and serves as a handle, the rest, about twice as long, is square and tapered to a fine point. The first holes being so far worn as to be unfit for bearing further reduction, the next of them, become likewise wider, supply their place, and are themselves supplied by the succeeding ones to the end, one hole in each plate thus, of course, becoming useless. Great accuracy and dexterity is required in adapting the hole to the wire that the latter may not pass too easily nor so stiffly as to endanger its breaking. For determining this point with the greater accuracy, the workman uses an instrument called a *size*, consisting of a brass plate on which is measured, by means of notches cut at one end, the increase which a certain length of wire should gain in passing through a fresh hole, and if the wire is found to stretch too little or too much, the hole is contracted or widened accordingly. There are also other instruments for measuring the degree of fineness of the wire itself, such as slits of different widths cut in polished iron rings, &c., which serve as gauges for this measurement.

The above means being provided, the wiredrawer's process commences with annealing the large wire received from the refiner, which is performed by placing it coiled upon lighted charcoal in a cylindrical cavity called the *pit* made for the purpose, and throwing more burning charcoal over it; the pit having no aperture at the bottom to admit air, the fire burns slowly, affording only sufficient heat to make the metal red hot without endangering its melting.

When it is cooled by being quenched in water, one end of it is passed through the first hole in the thick plate and fastened to an upright wooden cylinder six or eight inches in diameter, in the top of the cylinder are fixed two staples, and through these the long arm of the handle passes, by which the cylinder is turned on its axis by several men. In the continuation of this part of the process, the wire is frequently annealed and quenched, after passing through every hole or every other hole till it is brought to about the size of the small end of a tobacco pipe; and in this state it is cut into portions for the fine wiredrawers.

In this last part of the wiredrawing process it is not necessary to anneal, but it is still required to wax the wire at every hole; and as in this state much less force is required for drawing it through the plate, a different instrument is therefore used. A kind of wheel or circular piece of wood, much wider than the foregoing cylinder, is placed horizontally, having in its upper surface small holes at different distances from the axis, and into one or another of these, according to the force required, is occasionally inserted the point of an upright handle, whose upper end is received in a hole made in a cross bar above. From this the wire is wound off upon a smaller cylinder called a *rocket*, placed on the spindle of a spinning wheel; and this last cylinder being fixed on its axis behind the plate, the wire is again drawn

Mechanical
Processes.

Manufac-
tures.

through upon the first, and as it is now brought to the proper fineness, it is annealed to fit it for the flatting-mill. This annealing is performed in a manner rather different from the former, and with much less heat, for if the wire were now made red hot it would entirely lose its golden colour, and become black, bluish, or white, a fault frequently found in different parcels of gilt wire. It is now wound upon a large copper bobbin, which is set upright, some lighted charcoal or small coal placed round it and brought gradually nearer and nearer, and some small coals are put into the cavity of the bobbin; the wire must be carefully watched, and as soon as it appears of a proper colour it must be removed from the heat. This operation requires the greatest care, and is generally performed by the master: though the wire in a great measure retains the springiness which it had acquired in the drawing, yet it is not so soft as it might be made in a greater heat; it is nevertheless sufficiently so for yielding with ease to the flatting-mill.

The flat-
ting-mill.

(934.) The flatting-mill consists of two rollers, turned in a lathe to perfect roundness, exquisitely polished, placed with their axes parallel one over another, set by screws till their circumference comes almost in contact, and both are made to go round by one handle; the lowermost is about ten inches in diameter, the upper is commonly a little more than two, though some make it considerably larger, and indeed it would be more convenient if made as large, or nearly so, as the lower; their width and thickness are about an inch and a quarter. The wire unwinding from the bobbin, and passing first between the leaves of an old book pressed by a small weight which keeps it somewhat tight, and then through a narrow slit in an upright piece of wood called a catch, which gives notice of any knot or doubling, is directed, by means of a small conical hole in a piece of iron termed a guide, to any particular part of the width of the rolls, so that, should there be any imperfections or inequalities of the surface, the wire may be kept from those parts, and when one part is soiled by the passage of a length of wire, the wire may be shifted; till the whole width of the rolls being soiled, so as to require being cleaned and polished anew with the fine powder called putty, prepared by calcining a mixture of lead and tin: the workmen value the rolls from the number of places which the wire can thus be shifted to; good rolls will receive forty threads. The wire flattened between the rolls is wound again as it comes through on a bobbin, which is turned by a wheel fixed on the axis of one of the rolls, and so proportioned that the motion of the bobbin just keeps pace with that of the rolls.

Gilding.

Gilding of
the Ro-
mans.

(935.) The Art of gilding is intimately connected with that of gold beating, the latter indeed being useful only so far as it facilitates the former. A description of this process will therefore form a proper sequel to the preceding article. It has been said that, although the Ancients were not unacquainted with this Art, they possessed it in a very inferior degree compared with the Moderns, the leaves of gold they employed having been so thick that the process was very expensive and very rare; and, according to Pliny, the first gilding seen in Rome was subsequently to the destruction of Carthage, when the practice commenced of gilding the ceilings of temples and palaces, the Capitol being the first place on which this enrichment was bestowed.

VOL. VIII.

There are two sorts of gilding which differ essentially from each other, *i. e.* by metallic gold and by amalgam. The former is also divisible into two branches, according as it is effected by heat or applied cold.

Mechanical
Processes.

Gilding by amalgam.—This is practised only on metals, and is effected by heating pure quicksilver in a clean crucible, and when near boiling putting in about a sixth of its weight of fine gold in thin plates heated red hot, they are then stirred gently about till the gold is found melted and incorporated with the mercury. It is then allowed to cool, and put into a piece of soft leather, and by gradual pressure the fluid part of the amalgam, consisting almost entirely of mercury, may be forced through the pores of the leather, while the gold, combined with about twice its weight of mercury, remains behind, forming a yellowish silvery mass of about the consistence of soft butter, and with this the process (when the metal to be gilt is silver, copper, or alloys of copper with zinc) is, as nearly as the nature of the article will admit, conducted in a similar manner to that described for gilding buttons under the article *Button-making*. (685.)

Gilding by
amalgam.

Iron and steel also are sometimes gilded by amalgam, and sometimes by means of metallic gold, but in either way considerable difficulty is incurred. When the process is attempted with gold leaf, the difficulty consists in preventing oxidation during the heating of the iron; moreover, the temper of the metal, in such cases as sword-blades, daggers, &c., is liable to injury from the heat necessary to be employed, and this difficulty is by no means lessened by the use of amalgam. When the latter method is employed, a solution of mercury in nitrous acid, technically called quicksilver water, is applied to the parts intended to be gilded; then the acid, having an affinity for the iron, seizes a portion of it and deposits in its place a thin coating of mercury, which unites with the gold amalgam afterwards employed; but here the surface of the metal is injured, and the union of the mercury is very slight, so that a bright and durable gilding is not to be obtained.

Gilding
iron and
steel.

Another process, very little preferable to the former, is by means of sulphate of copper, a solution of which is applied with a camel-hair pencil to the parts intended to be gilt, when a chemical action similar to the former takes place and a coating of copper is precipitated, and, copper having an affinity for the mercury, a sort of union takes place between the steel and the gold; but whichever of these methods is adopted the surface is injured by the acid, and the temper by the heat which is necessary for driving off the mercury. Artists, therefore, generally, with all its disadvantages, prefer the process first mentioned, that is by heat and simply burning down the leaf.

Another
process.

Another process has been recommended which is supposed to be preferable to either before mentioned, for which we are indebted to an article in the *Phil. Mag.* vol. xi. Here the first part of the process consists in pouring over a solution of gold in nitro-muriatic acid and about twice as much ether, which must be done with caution and in a large vessel; the liquids must be shaken as soon as the mixture is at rest, and the ether will then separate itself from the nitro-muriatic acid and float on the surface. The nitro-muriatic acid becomes more transparent and the ether darker than they were before, the ether having taken the gold with the acid. The whole mixture is then poured into a glass funnel the lower aperture of which is small, but this aperture must not be opened

A third
process.

Manufac-
tures.

till the fluids have completely separated from each other. It is then to be opened, by which means the liquid which has taken the lowest place by its greater gravity, viz., the nitro-muriatic acid, will run off, after which the aperture is to be shut, and the funnel will then be found to contain nothing but ether mixed with the gold, which is to be put into well-closed bottles and preserved for use.

In order to gild iron or steel, the metal must first be polished with the finest emery, or rather with the finest *p* *crocus martis*, or *colcothar of vitriol*, and common brandy. The auriferous ether is then to be applied with a small brush, which soon evaporates, and the gold remains on the surface of the metal, which may then be put into the fire and afterwards polished. By means of this auriferous ether all kinds of figures may be delineated by employing a pen or fine brush, and it is in this manner, we believe, that the Sohlinger sabre blades are gilded.

Cold
gilding.

Cold gilding on silver.—This can be speedily done and with little trouble by dissolving gold in the nitro-muriatic acid, and dipping some linen rags into the solution; they are then to be burned, and the ashes, which will be very black and heavier than common, carefully preserved; they are then to be rubbed on the surface of the silver with the finger or a piece of leather or cork; by so doing the particles of gold they contain will be left on the surface of the metal. If the silver be then washed so as to remove the remaining part of the ashes, it will have scarcely any appearance of gilding, but on being burnished it will assume a beautiful gold colour: this method of gilding is very easy and requires very little gold.

Gilding of
brass.

Gilding of brass.—Five instruments of brass, in order that their surface may be kept longer clean, may be gilded in the following manner: saturated solution of gold is to be evaporated to the consistence of oil; it must be allowed to shoot into crystals which are to be dissolved in pure water, and the articles to be gilded being immersed in it, are then to be washed in pure water and afterwards burnished: this process may be repeated till the articles have been well gilt. A solution of gold crystals is preferred to a mere solution of gold, because in the latter there is always a portion of free acid which will not fail to exercise more or less action on the surface of the brass or copper and injure its surface.

Lackering
brass.

(936.) *Lackering of brass.*—The gilded appearance sometimes given to brass articles is produced by means of a solution of gum lac in spirits of wine, with which they are rubbed over; while the lac lasts they retain their splendour, but it will soon be destroyed if a strong brush or chalk are used in cleaning them. A varnish of this kind may be prepared in the following manner: two ounces of very pure and fine gum lac is to be dissolved in forty-eight ounces of alcohol, and the solution placed in a sand bath exposed to a moderate heat; to prevent the too abundant evaporation of the spirits of wine, as well as the bursting of the glass, a piece of bladder ought to be bound over the latter, and a few holes made in it with a needle; in another glass is to be dissolved, in the same quantity of spirits of wine, an ounce of dragon's blood in grains; now both the solutions being completed, they are to be mixed together, and three grains of yellow woad put to them, and to be allowed to remain twelve hours in a moderate heat, after which the liquor must be strained through a filtering paper and put into a glass bottle for use. To give this lac varnish a high colour, yellow woad is preferable to

every other substance, but if it is required to be pale and not to change the colour of the brass the yellow may be omitted, but if a stronger colour be required a half more of the yellow woad may be added.

Mechanical
Processes.

Gun-making.

(937.) The term gun-making is generally applied to the manufacturing of small arms only, such as muskets, fowling-pieces, pistols, &c. The making of the larger arms, as cannon, mortars, howitzers, and carronades, being commonly classed under the terms cannon-founding and boring. Gunpowder for the purpose of military attack and defence was first applied to the larger arms, the history of which has been traced under GUNPOWDER; and it appears that, very soon after this period, the smaller arm, or musket, was invented, but it still exceeded considerably in weight those found most effective in the present day, the bore having been much larger, and the weight so much greater that it was obliged to be supported on a fork when fired, which latter operation was effected by a match with priming powder; and under this form of match lock (although made much lighter) it remained in England till about the reign of Charles II., who, in 1638, granted a Charter to the Gunsmiths of London, by the name of Master, Warden, and Society of Gun-makers, and directed that, in future, the barrel should not be less than three feet in length, and the bore such as to carry a ball of which twelve should weigh a pound. The lock at this time was of the kind called the "wheel and snap lance." The invention of the flint and hammer lock succeeded this, but at what period it was introduced, or to whom we owe the invention, is not distinctly known. Beckmann, in his *History of Inventions*, says, "It is stated in the *History of the Brunswick Regiments*, that the soldiers of that Duchy first obtained, in 1687, flint locks instead of match locks;" but it is not said they were then first invented; indeed the immense variety of forms and gradations from one form to another is such as to make it extremely difficult to say when any particular form, or even a particular principle, was first employed. In the model room in the Repository at Woolwich is an extremely interesting collection of fire-arms and locks, from the first rude match lock to the present improved flint and percussion locks; but the different constructions are so blended that it is impossible to trace any very distinct step or improvement.

That the first means of discharge was with a match and priming powder is undoubted; and the next step seems to have been by attaching the match to a wheel, which might be turned round and the former thereby applied to the touchhole, so that a person might direct the gun and fire it at the same time. Next followed the wheel and fire-stone, the latter being screwed into the cock, and a steel plate or small wheel which could be cocked or wound up by a key. This fire-stone, however, was not at first of a vitreous nature or flint, like that at present used for striking fire, but a piece of compact pyrites; and as an instrument of such a kind was very liable to miss fire, a match was for a long time retained with the wheel, probably to the time of the invention of the flint lock.

Gun-making, in the larger manufactories, consists of several distinct operations, on each of which a different set of persons is employed, viz., the barrel-forging, borer and filer, lock-forging and filer, furniture-filer,

Gun-mak-
ing.
History of
the musket.

Practice of
gun-mak-
ing.

Manufactures.

ribber and breecher, rough stocker, screwer, polisher, and engraver, in all ten different parties, few of which can execute any branch of the Art except that in which they are engaged, at least they acquire, by this division of labour, a dexterity in one process which can scarcely be attained where a person is perpetually changing his occupation.

Forging the barrel.

(938.) *Barrel forging.*—In forming the common gun barrel the workman begins by heating and hammering out a bar of the best iron into the form of a flat ruler, thinner at the end intended for the muzzle, and thicker at that for the breech, the length, breadth, and thickness of the whole plate being regulated by the intended length, diameter, and weight of the barrel. This oblong plate is then, by repeated heating and hammering, turned round a cylindrical rod of steel or mandril, the diameter of which is considerably less than the intended bore of the barrel. The edges of the plate are made to overlap each other about half an inch, and are welded together by heating the tube in lengths of two or three inches at a time, and then hammering it with very brisk but moderate strokes upon an anvil which has a number of semicircular furrows in it adapted to barrels of different sizes.

The heat required for welding is the bright white heat which immediately precedes fusion, and at which the particles of the metal unite and blend so intimately with each other that, when properly managed, not a trace is left of their former separation. Every time the barrel is withdrawn from the forge, the workman strikes the end of it once or twice gently against the anvil in a horizontal direction; this operation, which is called jumping, serves to consolidate the particles of the metal more perfectly, as well as to disengage the scoria from the inside and outside of the tube and to obliterate any appearance of a seam. The mandril is then introduced into the bore or cavity, and the barrel being placed in one of the furrows or moulds of the anvil is hammered very briskly by two persons, the forger all the while turning it round in the mould, so that every part of the heated portion may come equally under the action of the hammer.

These heatings and hammerings are repeated until the whole of the barrel has undergone the same operation, and is rendered as perfectly continuous as if it had been bored out of a solid piece.

Pistol barrels.

Pistol barrels undergo the same process, except that those in particular which are to form pairs are forged in one piece, and are not cut asunder till after they have been bored, by which it is considered there is not only a saving of labour and material, but that greater accuracy is thus also obtained.

The barrel being completed to the extent above described is now to be finished by boring and filing or turning, as described below; but before explaining this process, it will be proper to speak of the twisted barrel, which is considered much superior to the common barrel, and is generally therefore preferred for fowling-pieces.

Twisted barrel.

(939.) The *twisted barrel* is forged in several pieces according to the following process, viz., four pieces of stub iron of two feet in length, half an inch in breadth, and two of the bars half an inch thick or more, according to the size of the barrel, are previously prepared, and an old gun barrel being welded to one of these to serve as a handle, it is heated and turned round like a cork-screw by means of the hammer and anvil, after which

the turns of the spiral are united by heating the tube a few inches at a time to a bright white heat, and by striking the end of it several times against the anvil in a horizontal direction with considerable force. This, as we have before said, is called jumping the barrel, and the heats given for that purpose are named jumping heats; a mandril is then introduced into the cavity, and a quick, light hammering is kept up on the welding part till the ridges raised at the seams by jumping are flattened and the piece appears sound; as soon as one bar is jumped and rounded in this manner, another is welded to it and treated in the same way till the four pieces are united and form one tube. The old barrel is then cut off as being no longer requisite, and the operation of heating and hammering is frequently repeated on its whole length, till its external figure is correctly acquired, and the metal has attained the desired closeness of texture and fibre.

Mechanical Processes.

Great care is necessary in this respect, in order to avoid the defects to which all gun barrels are liable; indeed, it is nearly impossible to say in any case that they have been avoided, and for this reason every barrel ought to be carefully proved before it is offered for sale.

The defects which barrels are subject to, the plain wrought ones in particular, are distinguished by the terms crack or *flaw*, and the *grey*; the former is a want of continuity on account of a defect of welding, which if detected in the proof* ought to lead to the condemnation of the barrel, although it is sometimes attempted to be mended. The latter is a small plate or scale which adheres to the barrel by a narrow neck, from which it spreads out as the head of a nail does from its shank, and when separated leaves a pit or hole in the metal; of these defects the grey is of the greatest consequence, and the most frequent, and is, when it occurs, a great disadvantage, by affording a lodgement for moisture and foulness which ultimately corrode the iron and

* The immense demand for muskets, and the consequent extent of the manufacture and receipt of them for the Government service, render it very essential that a well-regulated and careful mode of proof should be established. Accordingly, every musket received and passed at the Tower has undergone the following proof.

1. The barrel is charged with ten drachms of powder and a ball which fits the caliber, and two wads of brown paper; it is then laid on a bank and fired and left in that state for two days, to ascertain whether the damp of the powder has worked through any small crack. It is then washed and examined, and if found thus far good, it is marked with the King's proof mark.

2. Every piece is again examined after being sighted, and a single crown is then marked upon them.

3. They are again examined, when the break-offs are fitted before they are stocked.

4. The locks, bayonets, ramrods, brass-work, &c., are separately viewed.

5. The stocks are viewed when in a rough state, to see that the walnut is of good heart, and again when in a more forward state, and are then finally marked with the storekeeper's hammer, and entered on his books.

As there are thus several viewers, each has a particular mark, so that any defect passed by him may be traced to him in any subsequent stage.

The immense number of arms received and issued by the British Government may be estimated by the following authentic statement:

There were issued between the years 1803 and 1816	
Muskets	3,227,716
Carbines	118,103
Rifles	27,895
Pistols	203,266

In 1813, the allies of Great Britain were supplied with 500,000 muskets.

In 1815, there were at one time 1000 muskets per diem manufactured in Birmingham.

The number of muskets on store at the Tower is about 738,000.

Manufac-
tures.

enlarge the bore till the barrel bursts or becomes unsafe.

It is also a circumstance of considerable importance with respect to the excellence of a barrel, that it should be forged as nearly as possible to its weight when finished, so that very little may be taken away in the boring and filing, for as the outer surface, by having undergone the action of the hammer more immediately than any other part, is rendered more compact and dense, as little of it as possible should therefore be removed. Such is also the case, although in a less degree, with regard to that portion of the middle of the barrel which is to be cut out by the boring instrument.

Double bar-
rels.

Double barrels, or those intended for a double-barrelled piece, after having been dressed to their proper thickness, which is generally less than for single barrels, are filed flat on the sides that are to join each other, so that they may sit close together. Two corresponding notches are, then made at the muzzle and breech of each barrel, and into these are fitted two small pieces of iron to hold them more strongly together. The barrels being united by turning the parts which touch, the ribs are fitted in and made fast by the same means. These ribs are the triangular pieces of iron which are placed between the barrels, running on the upper and under sides their whole length, and serving to hold them more firmly together. The under rib is a recent improvement, serving more effectually than the single rib to prevent the barrels from warping.

(940.) *Indian gun barrels*.—The following description of the Indian method of working gun barrels in imitation of the Damascus steel, given by Captain Bagnold of Bombay, and presented by his brother Mr. J. M. Bagnold to the Society of Arts, will be interesting to the reader.

"The gun barrels made at Bombay in imitation of Damascus iron, so much valued by the Orientals for the beauty of their twist, are manufactured of iron hoops obtained from European casks, mostly British. The more these hoops are corroded with rust, the more are they acceptable to the workman; should there be any deficiency of this necessary oxidation, they are regularly exposed to moisture until they are sufficiently prepared for welding. Being cut into lengths of about twelve inches, they are formed into a pile an inch or an inch and a half high, laying the edges straight so as not to overlap each other; a longer piece is then so fitted as to return over each end and hold the whole together in the fire. This pile is then heated to a welding heat, and drawn out into a bar of about an inch wide and one-third of an inch thick; it is then doubled up in three or more lengths, and again welded and drawn out as before; and this operation is repeated generally to the third or fourth time, according to the degree of fineness of twist required. The bar is then to be heated about a third of its length at a time, and, being struck on the edge, is flattened the contrary way to that of the stratification. This part of the operation brings the wire or vein outwards upon the strap. The barrel is then forged in the usual way, but much more jumping is used than in the English method, in order to render the twist finer. The most careful workmen always make a practice of covering the part exposed to the fire with a lute composed of mud, clay, and the dung of cows or horses, in order to guard against any unnecessary oxidation of the metal. When the barrel is completed, the twist is raised by laying the barrel from one to five days either

in vinegar, or a solution of the sulphate of iron; this process is called the *wire twist*.

Mechanical
Processes.

"To produce the *curl*, the bars or straps are drawn into bars about three-quarters of an inch square, and twisted some to the right and others to the left hand; two of each sort are then welded together, doubled and drawn out as before described; and, according to the skill and experience of the workman, any intricacy of twist is produced by this drawing out, doubling, and twisting.

"Sometimes, to save trouble and economize the iron thus prepared, the artist will rough file an English barrel, weld a strap of Damascus iron spirally round it, or lay several straps longitudinally along it and weld it on. A native artist never works with pit coal under any consideration, charcoal from light wood forms his only fuel."

(941.) *Boring*.—The next operation is that of boring, in order to give to the barrel its proper caliber. The boring bit is a rod of iron somewhat longer than the barrel, one end being made to fit the socket of the crank, and the other being furnished with a cylindrical plug of tempered steel about an inch and a half in length, and having its surface cut in the manner of a perpetual screw, the threads being flat, about a quarter of an inch in breadth, and running with very little obliquity. This form gives the bit a very strong hold of the metal, and the threads being sharp at the edges, scoop out and remove every roughness and inequality from the inside of the barrel, and render the cavity smooth and equal throughout. A number of bits, each a little larger than the preceding one, are afterwards successively passed through the barrel in the same way, until it has acquired the intended caliber. The equality of the bore is of great moment, and it may be tried with tolerable accuracy, by means of a plug of lead cast on a rod of iron or wood, or even by a musket ball, filed so as to fit the bore exactly, and pushed through the barrel by the ramrod, care being taken not to use an iron ramrod or much force, lest the ball be flattened and an artificial difficulty created.

The gunsmiths afterwards polish the barrel; and it is then in a condition to receive its proper form and proportions externally by means of the file. To do this with accuracy, four flat sides or faces are first formed, then eight, then sixteen, and so on, until it is made quite round, except the reinforced part, which, in most of the modern work, is left with eight sides.

It is absolutely necessary to the soundness of a barrel that it should be of an equal thickness on every side, or, in the language of the workmen, a barrel ought to be perfectly upright. To accomplish this the gunsmiths sometimes employ an instrument which they call a "compass," consisting of an iron rod bent so as to form two parallel branches about an inch distant from each other. One of these branches is introduced into the barrel and kept closely applied to the side by means of one or more springs with which it is furnished; the other branch descends parallel to this on the outside, and has several screws passing through it with their points directed to the barrel. By screwing these until their points touch the surface of the barrel, and then turning the instrument round within the bore, it is seen where the metal is too thick, and how much it must be reduced in order to render every part of the barrel perfectly equal throughout its circumference.

A more perfect way of accomplishing this object, how-

Manufactures.

ever, is, after the barrels are bored true inside, to introduce two perfectly cylindrical mandrils, one at each end, to put them into a lathe, and to turn the outside to the proper dimensions.

Breeching.

(942.) *Breeching of guns.*—The barrels being thus far advanced, they have next to be breeched, which is done by screwing in a plug of iron at the end, in which is formed the chamber and vent. The screw is formed in the barrel first by means of a tool or conical tap of tempered steel, having upon its surface the proper threads; this being introduced into the barrel is turned from right to left and back again, till it has marked out three or four threads of the intended screw; another less conical tap is then introduced, and when this has carried on the impression of the screw so far as it is intended to go, a third tap is employed, which is nearly cylindrical, and scarcely differs from the plug of the breech, which is intended to fill the screw thus formed in the barrel. This screw is cut by a screw plate of tempered steel, or otherwise, according to the intended perfection of the piece when finished. Seven or eight threads are generally thought sufficient, and when cut neat and sharp it is case-hardened and introduced. In fig. 1, plate lxvii., is shown a section of the breech, patented by Mr. Nock, with the chamber *c*, ante-chamber *d*, and vent plug *f*. The particular form of breeching, however, differs considerably in different manufactories.

Pl. lxvii.
Fig. 1.

Colouring.

Colouring the barrel.—The next operation is that of giving to the outside of the barrel its proper colour, previously to which it is polished with fine emery and oil, until it presents to the eye through its whole length, and in whatever manner it is observed, a perfectly smooth and bright surface. In this state it may be given either the fine blue colour of tempered steel, or the bronze colour; the former by heating the barrel, but the latter, which is now generally preferred, as follows. In the bright state above described, the barrel is rubbed over with aqua fortis diluted with water, and in this way laid by till a complete coat of rust is formed upon its surface; a little oil is then applied, which being rubbed dry is polished by means of a hard brush and bee's-wax.

Rifle guns.

(943.) *Rifle guns.*—We have preferred to complete the account of the entire process of making gun barrels of the more usual kind before describing the rifle barrel, which is comparatively a modern improvement, generally attributed to the Germans, who are extremely fond of its use, as are also the Americans. The process of rifling is as follows. The barrel being forged and bored, as described in the preceding columns, is placed on the rifling machine, which is an instrument formed on a square plank of wood, seven feet long, to which is fitted a tube about one inch in diameter, with spiral grooves deeply cut internally through its whole length, and to which is attached a circular plate about five inches in diameter, accurately divided, in concentric circles, into from five to ten equal parts, and supported by two rings fixed to the plank on which it revolves: an arm connected with the driving plate, and pierced with holes through which a pin is passed, regulates the change of the tube in giving the required number of rifles to the barrel. An iron rod, with a movable handle at one end and a steel cutter in the other, passes through the rifling tube; this rod is covered with a core of lead one foot in length, and the barrel is firmly fixed by means of two rings on the plank, standing in a straight line to the tube; the rod is then repeatedly drawn through the whole length

of the barrel till the cutter has formed one groove to the proper depth; the pin being shifted to another hole in the dividing plate, the operation of grooving is continued till the whole number required is completed. The barrel is then taken out of the machine, and is finished by casting, on the end of a small iron rod, a core of lead, which, when coated with fine emery and oil, is drawn for a length of time by the workman from one end of the barrel to the other till the latter has acquired a high degree of smoothness and polish; it then passes into the hands of other workmen to be completed the same as other pieces.

Mechanical Processes.

(944.) *Theory of the rifle.*—Although the great advantage of rifling is universally admitted, considerable difference of opinion has existed as to the cause of this advantage, some attributing it to one principle and others to a different one. The first writer who undertook to examine the subject with proper attention was Mr. Robins, and he began by inquiring first into the cause of deflection in the common barrel. With this view he secured a musket barrel upon a block of wood, and firing with a ball at a board a foot square at 60 yards' distance, he found that it missed the board only once in sixteen successive discharges; yet when fired with a smaller charge at a distance of 760 yards, the ball was thrown sometimes 100 yards to the right or left of the line in which it was pointed. The direction upwards and downwards was also found equally uncertain, the ball in some discharges having struck the ground 200 yards nearer the piece than it did at others.

Robins's theory of the rifle.

It is not difficult to account for these irregularities; they doubtless proceed from the impossibility of fitting a ball so accurately to any plain barrel that it will not rub more against one side of the barrel than another in its passage through it. Whatever side, therefore, of the muzzle the ball is last in contact with on quitting the piece, it will acquire a whirling motion towards that side, and will be found to bend the line of its flight in the same direction, whether it be upwards or downwards, to the right or left, or obliquely, partaking in some degree of both; and after quitting the barrel, this deflection, which though in the first instance it is but trifling, is still further increased by the resistance of the air; this being greatest on that side where the whirling motion conspires with the progressive one, and least on that side where it is opposed to it. Thus if the ball in its passage out rubs against the left side of the barrel, it will whirl towards that side; and as the right side of the ball will, therefore, turn up against the air during its flight, the resistance of the air will become greater on the right side, and the ball be forced away to the left, which was the direction it whirled in. If the axis about which the rotary motion of the ball is made preserved its position during the whole of the flight, the deflection would be in the same direction from one end of the track to the other, though it is obvious that the quantity of this deflection would still not be proportional to the distance; for if all resistance of the ball were to cease at any part of its flight, still the ball would necessarily pursue the line in which it then moved, and the deflection be double at a double distance, treble at a treble distance, and so on. But as this resistance does not cease, but continues to act upon the ball throughout its whole flight, (though less in the latter part of it than at the commencement, in consequence of the decrease of velocity,) it is obvious that the deflection of the ball will be accelerated at every

Manufactures.

instant, and consequently increase in a greater proportion than the distance, as we have seen it has been found to do from the experiments above alluded to. It happens, however, from various accidental circumstances, that the axis of the ball's rotation frequently changes its position several times during the flight; so that the ball, instead of bending its course uniformly in the same direction, often describes a track variously contorted. So great, however, is the tendency of the ball to deflect itself against the side it rubs against, that it has been said, though we never saw the experiments authenticated, that a ball, when fired out of a barrel bent towards the left hand, and which will, therefore, be thrown from the piece in the direction of the bend, yet as the ball in this case will be forced to rub against the right side of the muzzle, and thus turn its left side up against the air, so it will be found to alter its course during the flight, and bend towards the right hand, so as to fall a considerable way to the right hand of the line in which the piece was pointed.

It will readily appear, therefore, from what has been stated, that these variations will be more frequent and considerable when the ball runs very loose in the piece, or when, from any roughness on its surface, or on the middle of the barrel, a considerable degree of friction takes place between them. With a view to prevent friction, it has been proposed to grease the ball; but this, we should imagine, would be of very little service. All that can be done in a plain barrel is to have the ball cast very solid and true, and afterwards milled, in the same manner as is now practised upon shot; the barrel also should be very smooth on the inside, and the ball fit in very accurately, so as to leave scarcely any windage; yet, with all these precautions, it is very difficult, we may say impossible, to prevent it entirely; for gravity will constantly act, and friction on the under side will naturally be occasioned by the weight of the ball. In fact, when we consider the causes of the aberration in the flight of balls, it will be pretty evident that the only means of correcting it is by preventing the ball from rubbing more against one side of the barrel than another in passing through it, and by giving to the bullet a motion which will counteract every accidental one, and preserve its direction by making the resistance of the air upon the fore part continue the same during its whole flight; that is, by giving it a rotary motion perpendicular to the line of direction.

Construction of gun locks.

(945.) *Gun lock.*—We have already, at the commencement of GUN, mentioned slightly the great variation which the form of the lock has undergone; to enter into a more particular description of the ancient contrivances of this kind would, it is conceived, but little interest the reader. We shall, therefore, simply refer to the common flint and steel lock and the percussion lock, the latter being comparatively a recent invention, although it has itself already undergone many changes. The common flint and steel lock is represented in fig. 2, 3, the former showing the works inside, and the latter the outside, the operation of which is too well known to require any particular description.

Pl. lxvii.
Fig. 2, 3.

Percussion lock by J. Manton.

Fig. 4, 5, 6.

The percussion lock was first invented by Rev. Mr. Forsyth, Minister of Belhelvie in Scotland; but the original form as given to it by the inventor is now wholly laid aside, as are several others which have succeeded it. One of the most recent, and which appears to possess many advantages, is a patent invention by Joseph Manton, the well-known gunsmith. This is represented in fig. 4, 5, 6,

&c., in which, instead of the usual percussion cap, a plug, shown in section in fig. 4, is employed; the centre part *a* being an iron pin, below which, in the small recess at *c*, the percussion composition is contained, slightly covered with a cement to preserve it in its place; *b b* is a plug of box wood, an elevation of the same is seen in fig. 5; fig. 6 shows the lock with a socket *s* attached, *h* being the hammer. The central hole in the socket is formed conical like the plug, and is precisely of the same size, with a form of a screw inside, so that by a slight pressure and turn of the hand, when the plug is introduced, it is safely retained in its place, and may remain there without any fear of displacement, or of injury from the weather. The gun is fired in the usual manner, when the force of the explosion splits the box plug, which falls out by a slight turn given to the musket; another plug may be then immediately introduced. At present, the percussion lock has not been introduced into the British army, but from experiments which have been made on this lock by authority of the Ordnance Board, at Woolwich, it is probable such may be soon the case. One objection to the introduction of the common cap was, that it was so small it could scarcely be felt when the hands were very cold and was likely to be dropped and lost; this objection is here avoided by the plug being of the full size shown in the figure; and from the results obtained in the experiments above alluded to its quickness of firing very far exceeds that of the common cap, in consequence of the explosion being placed so near the powder. We give the two following Tables from a report of Captain J. A. Chalmers of the Royal Artillery, which with other particulars he was authorized to furnish the patentee.

Mechanical Processes.

TABLE I.—Showing the comparative Failures in Forty Rounds of Ball Cartridges from each of six Muskets on Rivier's Percussion Cap, Manton's Percussion Plug, and Lovell's Flint and Steel Lock Principles, in heavy Rain. Comparative experiments on different locks.

N. B. After the sixty-ninth round the muskets were loaded and piled in the open air, they remained so three hours, when the practice was resumed without cleaning the muskets. The flints in Lovell's muskets were changed after every twenty rounds, and in addition to replace broken ones.

In Rivier's four primes were dropped; in Manton's two during the practice.

Locks for ships' guns.

(946.) *Locks for ship ordnance.*—Till of late years ships' guns were fired by slow match and priming powder, but subsequently steel and flint locks have been employed, which resemble in a great measure, except in size, the common musket lock, and still more recently attempts have been made to introduce the percussion principle. As first tried by the late Sir William Congreve, the hammer was simply attached to the breech of the gun, forming a kind of bent lever turning on a joint at the angle; to the shorter arm a string was attached, by a smart pull at which the hammer turned on its joint and struck the percussion cap over the vent and thus fired the gun; but it was found that the sudden return of the hammer from the explosive force of the powder was such as generally to destroy it in a very short time. To remedy this defect, Mr. James Marsh, an ingenious artisan in the Royal Arsenal, has invented a different tube, viz., one which is bent at right angles, whereby the percussion powder is not placed over the vent but on the vent field, whereby the former evil is avoided, and, as far as the experiment goes, they promise to be completely successful.

Gun-flints.

(947.) *Gun-flints.*—The art of forming gun-flints, as appears by the account given by Beckmann, was kept as a great secret in France and Germany, although we see it frequently publicly exhibited in different parts of England. The masses of flint which are best fitted for this purpose are of a convex surface approaching to globular. The knobbed and branched flints are commonly full of imperfections. The best flint nodules are generally between two and twenty pounds in weight. They

should be unctuous or rather shining internally, with a grain so fine as to be imperceptible to the eye, the colour should be uniform in the same nodule, and may vary from honey-yellow to a blackish-brown; it is likewise necessary that the fracture should be smooth and equal, the fragments slightly conchoidal, and the transparency should be such as to allow letters to be distinguished through a thickness of one-fourth of a line when laid close to the paper. Flints which do not possess these properties, either naturally or after a long exposure to the air, are rejected by the workmen.

Mechanical Processes.

Four tools are necessary in the manufacture of gun-flints; first, an iron hammer with a square head, a handle seven or eight inches long, and not exceeding two pounds in weight. This instrument is shown in fig. 7, plate lxvii. Secondly, a hammer of well-hardened steel with two points, a handle seven inches long, and from ten to sixteen ounces in weight. The handle must pass through in the same manner that the two points may be nearer the hand of the workman than the centre of gravity of the mass. This hammer is represented in fig. 8. Thirdly, a disk hammer or roller, like a solid wheel or the section of a cylinder, two inches and four lines in diameter, and not exceeding twelve ounces in weight. It is made of steel not hardened, and has a handle six inches long, which passes through a square hole in the centre. It is shown in fig. 9. Fourthly, a chisel tapering and bevelled at both ends, which should be made of steel not hardened, and six, seven, or eight inches long, and two inches wide. This chisel is represented in fig. 10; it is set upon a wooden block which is also used as a bench for the workmen; a file is necessary for restoring the edge of the chisel. With these tools the flints are formed in the following manner, which we have abridged from Dolomieu's Memoir.

Description of tools.

Pl. lxvii. Fig. 7, 8, 9, 10.

1. *To break the block.*—The workman seated on the ground places the nodule of flint on his left thigh, and applies slight strokes with the square hammer to divide it into smaller pieces of about a pound and a half each with broad surfaces and almost even fracture.

Processes described.

2. *To cleave or chip the flint.*—The workman holds the piece of flint in his left hand, not supported, and strikes with the pointed hammer, fig. 8, on the edges of the great planes produced by the first breaking, by which means the white coating of the flint is removed in the form of small scales, and the mass of flint itself laid bare in the manner represented, (fig. 11,) after which he continues to chip off similar scaly portions from the pure mass of the flint; these scaly portions are nearly one inch and a half wide, two inches and a half long, and their thickness in the middle is of about two lines. They are slightly convex below, and consequently leave in the part of the flint from which they are separated a space slightly concave, longitudinally bordered by two rather projecting straight lines or ridges, fig. 12. These ridges, produced by the separation of the two scales, must naturally constitute nearly the middle of the subsequent piece, and such scales alone as have their ridges thus placed in the middle are fit to be made into gun-flints. In this manner the workmen continue to split or chip the mass of flint in various directions, until the defects usually found in the interior render it impossible to make the fracture required, or until the piece is reduced too much to receive the small blows by which the flint is divided.

Fig. 11, 12.

3. *To shape the gun-flint.*—Five different parts may

Manufac-
tures.

be distinguished in a gun-flint. First, the sloping face or bevel part which is impelled against the hammer of the lock of the gun. Its width should be about three-twelfths of an inch, if it were broader it would be too liable to break, and if more obtuse, the scintillation would be less brisk. Secondly, the sides are lateral ridges, which are always rather irregular. Thirdly, the back or the part opposite the tapering edge; this is the thickest part of the flint. Fourthly, the under surface, which is uninterrupted and rather convex; and fifthly, the upper face or small square facet between the tapering edge and the back which receives the upper claw of the cock; it is slightly concave. In order to fashion the flint, those scales are selected that have at least one of the above-mentioned longitudinal ridges. The workman fixes on one of the tapering borders to form the striking edge, after which the two sides of the stone that are to form the lateral edges, as well as the part which is to form the back, are successively placed on the edge of the chisel in such a manner that the convex surface of the flint, which rests on the forefinger of his left hand, is turned towards that tool; he then with the tool, fig. 10, applies some slight strokes to the flint just opposite the edge of the chisel underneath, by which means the flint breaks exactly along the edge of the chisel.

4. *To trim the flint.*—The last operation is to trim or give the flint a smooth and equal edge; this is done by turning the stone, and placing the edge of its tapering end on the chisel, in which situation it is completed by five or six slight strokes with the round hammer. See fig. 13.

The whole operation of making a gun-flint is performed in less than one minute. A good workman is able to manufacture a thousand good chips or scales per day, (if the flint nodules be of a good quality,) and in the same manner he can fashion five hundred gun-flints in the same time, so that, in the space of three days, he is able to cleave and finish a thousand gun-flints without further assistance.

In this manner five or six blows with the hammer are sufficient to produce a perfection of figure which would require more than an hour's labour if the faces were formed by grinding them against harder substances; and less than a farthing will pay for a flint from the hand of the workman, though fifty times that sum would be insufficient to purchase it if it were formed in any other way.

When the gun-flints are completed, they are sorted into two classes, fine and common flints, and according to their application into flints for pistols, fowling-pieces, and muskets. A good gun-flint will give fifty strokes without being unfit for service. They are sold in France at from four-pence halfpenny to seven-pence per hundred; their cost is twice that in Italy; and in 1745, when they were exported from the Department of the Loire and Cher to Lyons, Strasburg, and St. Quintin, they cost twelve francs per thousand, or one shilling per hundred.

The manufacture of gun-flints in France employed above 800 of the inhabitants in the Communes of Noyers, Couffy, and Meunes, in the Department of the Loire and Cher. The mine, which is four leagues square, is thirty or forty feet deep, and 30,000,000 of flints manufactured here were stored up in 1794. They are also made in the Communes of Lye, in the Department of the Indre, of Maysse and St. Vincent, in the

Department of Ardeche, and at Cerilly, in the Department of the Yonne. Dolomieu received the information contained above from Stephen Buffet, who emigrated from the Commune of Meunes to the banks of the Seine, where he carried on his profession for above thirty years.

Gun-flints are made also in the territory of Vicenza and in one of the Cantons of Sicily. They were manufactured in great quantities at Stevensklint in Zeeland. There is a manufactory of flints at Purfleet in Kent, and they are likewise made in various other parts of England in very superior style.

See Dolomieu's Memoir in the *Mémoires de l'Institut*, vol. iii. p. 148; in the *Journal des Mines*, No. 33, p. 693; and in Nicholson's *Journal*, vol. i. Svo. p. 88; in the *Journal des Mines*, No. 33, p. 713, 719, will also be found a Memoir by M. Solivet, and observations by M. Tonellier on the manufacture of gun-flints in the Commune of Cerilly. See also the *Hanoverian Magazine* for 1772; and Beckmann, *History of Inventions*, vol. iv. p. 609, &c.

Nail-making.

(948.) As we intend only to describe in this section such mechanical processes as are effected by machinery, we might pass over unnoticed the old method of forging nails, but the article would, perhaps, in that case be thought somewhat incomplete; we therefore propose to describe the method of forging nails, but as concisely as possible. The iron used for these kinds of articles is not of the best quality; it is rolled first into thin bars, and then slit down into rods of proper size for different kinds of nails; a small forge and small pair of bellows only are required, and the work was therefore formerly, and is at present, where it is continued, carried on by nailers at their own cottages. The rods being very thin, three or more may be heated at a time; one of them having a good red heat is then taken out of the fire, and worked on an anvil to a square sharp point by a very few blows; the nailer now applies it over the edge of a fixed chisel, at a certain distance from which is a bar, so that by pushing the point against the bar and striking a single blow over the chisel the nail falls off into a tin pan; the lengths being thus all alike, the iron is still sufficiently hot to form another such piece, but the rod is then returned to the fire. The workman next with a pair of tongs takes up the nail and introduces its point into a square tapering hole made across through the end of an iron tool or mould, and by striking a blow or two on the end of the iron he flattens it down and forms the head, the intended figure of which is acquired by a few blows dexterously applied. This process is indeed conducted with surprising rapidity, the nailers by long practice having acquired a mechanical habit of forming an entire nail by a certain number of blows, and it is very rarely an unnecessary blow is given.

In the larger nails only one can be made and cut off at each time the iron is taken from the fire, because the workman would be unable to get the heading finished whilst the iron was sufficiently hot. The length of the nail, of whatever size, is regulated by a stop fixed at a certain distance from the edge of the chisel as above described, so that the point of the nail being applied to this determines the proper place for the edge of the chisel. The size of the mould withinside, and the dimensions to which the point of the nail is reduced by

Mechanical
Processes.

Nail-
making.

Old method
of forging.

Manufactures.

hammering, causes the cut end to project above the surface of the mould more or less; so that the head will be thicker or thinner, and have its quantity of metal regulated, by the degree of taper given to the point; therefore the art of the workman is displayed in striking with a due force, so that every nail shall be made of the same size by a certain number of blows. In this manner the greatest number of all nails were formerly made; but the great expense of labour has induced many manufacturers to turn their attention to inventions which would diminish the labour, whereby to enable them to bring their nails to the market at reduced prices, or of a better quality.

Nail-making by machinery.

(949.) These considerations have given rise to various patented inventions for nail-making machinery. The first was that of Mr. French, of Wimbourne in Stafford, in 1790; but it consisted of little more than working the hammer by water power, which enabled children to become nailers, as they had only to place the rods beneath the hammers; that is, one person brought the rod from the fire to another stationed before the hammer, who turned it about, formed the nail, and cut it off; it was then taken to the header, the operation being however still nearly as above described, except that the hammer in this case also was worked by the machinery.

About the same time, Mr. Clifford of Bristol took out a Patent with a like object, and, subsequently, another on a different principle.

Clifford's first Patent.

(950.) The first of these inventions consisted of making the nail in a die, that is, by having a die, or the impression of the nail to be cut, formed in one or more pieces of steel, and the iron of which the nails are to be formed drawn or rolled into the proper form and thickness, and by a force adapted to the purpose pressed into the cavity of the die, so as to form the nails either complete, or so nearly complete that they could be finished with very little labour.

The rollers are described as being made of iron cased with steel, each of the same diameter, which is proportioned to the length and size of the nail intended to be made. Each roller should have a cog wheel on it, the cogs of one roller working into those of the other, so that both the rollers may perform the same exact revolution. One half the impress of the nail is to be cut in the surface of one roller, the other half in the other, whereby the two impressions form a cavity or die of the exact form of a nail, extending lengthways of the nail on the circumference of the rollers; and as many impressions of the same kind may be cut in the rollers, one at the end of the other, as will complete their circumference and continue the cavity all round the rollers, the point of one nail joining the head of the next, or the two points and two heads joining each other. The rollers must, in this as in other cases, be made to work very truly and closely to each other.

The mode of operation is this: a rod of iron, previously rolled or drawn to a convenient size, is to be heated, and, while hot, the end of it is put between the rollers into the cavity or die which forms the impression of the nail; the roller being now put in motion, will draw the iron through, and the pressing it into the cavities or dies forms the iron into nails, one joined to the other, which must afterwards be separated by means of instruments acting as nippers, shears, chisels, &c. The rollers, being made to work very closely to each other where the edge of the nail is formed, will prevent much of the metal from being pressed out on each side of the

nail, and what is pressed out may be cut off by instruments adapted to the purpose. Several pairs of rollers may be made to work together, and each pair may have several rows or dies cut on them, so as to form the impression for several strings of nails; and a rod of iron being put into each of them will roll out as many strings of nails with one revolution of rollers. A pair of rollers may also have the greater part of their surface cut with dies, and a flat bar made to pass between the rollers so as to form sheet nails, all of them connected to one another by thin plates of the iron of which they are composed; this also would require each nail to be cut out or separated from the sheet by proper instruments.

Mechanical Processes.

(951.) Mr. Clifford's second invention consists, first, in drawing the iron or other metal into a tapering or wedge-like form, according to the length and thickness of the different sizes of nails to be made. Secondly, the nails are to be cut out of those wedge-like or tapering plates by means of a punch, the face of which is made according to the size, taper, and form of the nail to be cut out; as also having a hollow bolster, the hollow or aperture of which must also be made of the size and form of a nail, and consequently to fit and receive the punch above mentioned. The punch thus fitted to the bed, and sliding in a proper frame to keep it steady, will, by a blow or by pressure, cut or force part of the taper plate into and through the aperture of the bed fitting to it, and thereby form the nail. This operation is by the manufacturers of buckles, buttons, &c. called cutting out. Thirdly, to form the heads of horse nails, called rose heads, and others of nearly a similar kind: after the operations of drawing and cutting out, the nail is to be put into a heading tool, also called a bed, which bed receives the nails, excepting a small portion at the thick end, out of which the head is formed by a punch or die. This die, by blow or pressure, forms the head as required, and when the nails are made of hard iron, after they are cut in the way described, the thick end is made hot before they are put into the bed or heading tool. Fourthly, another method adopted in the manufacture of nails is by cutting them out of or from plates of equal thickness, and afterwards to point them either by hammer or other pressure. Fifthly, in making nails that are of a triangular form, the plate or strip of iron is pressed or stamped into a die having impressions cut to the form of such nails, after which they are cut out by a punch.

Clifford's second Patent.

Another Patent for forming nails was taken out by Willmore & Messrs. Willmore and Tonk, which is described as follows by the patentees.

"We take a nail rod suitable to the size of the intended nail, and, applying it to a common screw press mounted with proper cutters, cut off from the end of the rod two pieces at once, obliquely across the rod in one place, and directly across it in another, as is shown in fig. 1, plate lxviii. at *a e* and *b*. Two studs or stops are set up, one at *c* and the other at *d*, which are attached to the press, and are adjustable by screws or other means, the stud *c* being adjustable or movable in the direction of the rod for the purpose of ascertaining the length of the nail, both *c* and *d* being adjustable in the cross direction of the rod, so that the latter being pressed gently always against *c*, and sideways against *c* and *d*, the obliquity of the cut, according to the kind of nail to be made, is thereby determined, as well as the length of the nail; the length of the two pieces may either be

Pl. lxviii. Fig. 1, 2.

Manufac-
tures.

nearly equal or unequal, by means of the said adjustments, as will be evident on due consideration. This may be called the first operation. The next is to anneal the pieces so cut off, if the iron should not be sufficiently malleable, which is done in the usual and well-known manner. The third operation is that of heading, which for clasp-headed nails consists of two parts, one for gathering and the other for forming the head of the nail. The first part of this operation is performed by putting a piece cut off the rod of iron, as before described, into a pair of clams, leaving as much of the thick end projecting above the clams as is sufficient to form the head. These clams, have steel bits let into them with sharp edges, which press only against the two opposite sides of the piece, and which have the effect of two chisels when the punch of the press is brought down upon the piece with considerable force, and raise or gather up iron on each side towards forming the head. The second part of this operation is to put the piece thus prepared into another pair of clams, having bits formed to correspond to the under side of the head; and the punch, having the impression of the upper side of the head engraved or sunk into it, is brought to press strongly upon the head in the clams, and thereby the clasp head is properly formed. For nails intended to have rose heads, or any other kind except clasp heads, the first part of the operation is not absolutely necessary, though we think it advisable to be done, but the bits, which for clasp nails must have sharp edges, must for other kind of nails have blunt edges, to prevent the under cutting. For the second part of this operation the piece is put either into a pair of clams or into the tool commonly called a bore, and then pressed with punches, properly engraved or sunk, according to the kind of head wanted. By the third operation the piece cut off the rod is formed something like a mortise chisel, and the next or fourth operation is to point it, which is done by putting the piece into a bed of steel, in which is cut a nick or groove *d*, having parallel sides, as in the plan C, fig. 2, but the bottom rising towards the end where the point of the nail is to be formed, as seen in the section B of the bed. The punch is shown at A, and the end which presses upon the point of the nail is made to project further than the other part, so as to meet the corresponding part of the bed when the punch is brought upon the nail. The groove or nick in the bed should be just wide enough to receive the piece easily, but it must prevent it from twisting when the impression is made. The piece is put twice into the nick, once with the chisel end lying horizontal, and next turned a quarter to press the chisel edge into a pointed form. If the nails, by the strong pressure which is necessary in this operation, should become too hard to clinch, we in such case anneal them in the ordinary way, which may be called the fifth operation.

"The third, fourth, and fifth operations above described are applied to nails or pieces cut off from the sheet or rolled iron in the ordinary way; but as they, in consequence of the fifth operation, which is necessary to give them the quality of clinching, are apt to be too soft to drive well, we apply a sixth operation, *viz.*, quenching them when red hot in water, or other proper fluid, which gives them stiffness enough to drive without destroying the quality of clinching.

"Fig. 3 shows a pair of clams with bits or dies let into them, which can be renewed from time to time with more ease and at less expense than by the usual method.

These bits are proper for the first part of the third operation. Mechanical Processes.

"Fig. 4 a pair of bits or dies proper for making either rose heads or flat heads.

"Fig. 5 a pair of bits or dies proper for the second part of the third operation for clasp-head nails: the dotted line shows the head of the nail."

(952.) Another Patent, taken out by Mr. Daniel Ledsam and W. Jones of Birmingham in 1827, is thus described in vol. xlv. of the *Repertory of Arts*. Ledsam's Patent.

The first part of the machinery consists of a frame, supported on two horizontal pivots, which carries two movable and two fixed cutters, (the edges of which come in contact so as to cut like the blades of scissors,) and is so placed beneath vertical rods of metal that are made to descend between the cutters as to nip off from them small portions of the metal in the shape of the brads or nails required.

The use of the cutter frame being suspended on pivots is to allow the edges of the cutter to be inclined a small degree to the rods, in order that the pieces nipped off from their extremities may be pointed, and, as the inclination of the frame is shifted alternately to opposite directions, the side of the rod, from which the point of the last brad was cut, becomes that from which the head of the next brad is divided, and so on in a regular order reversed at each vibration of the frame. To give this movement to the frame, a horizontal axle is made to revolve beneath it by mill-work, on which an eccentric wheel is fixed vertically, which acts between parallel arms, descending perpendicularly from one end of the cutter frame, and, in turning, forces them a certain distance from the axle, first to one side and then to the other; this movement causes the frame to make a similar change of position with regard to the horizontal line between its pivots. There is also a crank on the same axle which moves the acting cutters forwards and backwards by a short connecting rod, in the following manner. Each of these two cutters is fastened to a flat rectangular plate, the ends of which slide in grooves prepared for them in the inner sides of the vibrating frame; and in the middle between these plates a flat hinge (like a common door hinge) is placed with its sides jointed to the opposite plates, while its own "knuckle," or joint, is connected by its pivot with the connecting rod of the crank; by these means, when the crank ascends, the knuckle of the hinge is raised, and the two cutters and sliding plates are thereby made to approach the centre of the frame; and when again the crank descends in revolving, the knuckle of the hinge is drawn down to a level with the sliding plates, and they and the acting cutters, by the expansion of the sides of the hinge, are forced outward from the centre, over the edges of the fixed cutters, so as to nip off the portions of the metallic rods that constitute the brads or nails.

A variation of this latter part of the contrivance is described in the specification, in which the plates that hold the acting cutters, instead of sliding in grooves, are supported by vertical pieces that are joined to them at their upper ends, and at their lower ends to additional horizontal bars attached to the vibrating frame underneath; this appears to us a better method of effecting the intended movement than the first.

The eccentric wheel on the axle, by which the vibrating frame receives the movement from which it is denominated, is made to alter its degree of eccentricity by having a rectangular cavity cut through its middle, in

Manufactures.

which a piece of the same shape that surrounds the main axle is drawn further from the centre or pressed nearer to it, as required by a screw, whose extreme end is connected to it by a pin which passes across the side of a groove turned in it for that purpose, and has its stem inserted in a hole drilled for it through the thickness of the eccentric wheel in the direction of its diameter.

The metallic rods from which the nails or brads are cut, and which may be of iron, copper, brass, or other fit metals, are brought down between the acting and fixed cutters by weights of a due size, which slide down strong wires that are stretched from a rafter (apparently, from the drawing, placed across the upper part of the room in which the machine is fixed) to a frame; but the method in which they are fastened to this latter, and some other particulars of their arrangement, are not explained with any degree of accuracy in the specification. A considerable number of these wires and rods with their weights, shaped something like pistols, are represented in the drawing, while parallel to each other, to be acted on by one pair of cutters, which also seem to be an arrangement that is faulty either as to contrivance or with regard to its insertion in the specification.

The machine is made, when required to form the kind of brads called sparrow-bills, (which have a small projection from one side of their heads,) by a piece of metal in the nature of an inclined plane that rises from the fixed frame; and which, as this latter is moved up and down, comes in contact with the bars to which the lower ends of the wires that sustain the rod weights are fastened, and thereby presses them a very small distance to one side, which is necessary to preserve the portion of the rod intended for the projection of the sparrow-bill from the action of the cutters.

Weight of nails exported.

(953.) The great extent of the nail manufacture in this Country may be seen by the following Returns of iron exported in this form, besides the immense amount necessarily employed for home consumption. The export of nails from 1820 to 1831 was as below.

Years.	Tons of Nails exported.	Years.	Tons of Nails exported.
1820	2847	1826	3538
1821	3288	1827	3957
1822	3353	1828	4596
1823	3785	1829	4528

Needle-making.

Needle-making, old process.

(954.) In the manufacture of needles there is but little machinery employed, and there was formerly much less; for the wire having been first reduced to the proper dimensions by drawing was then cut to the proper lengths; these were flattened at one end to form the place for the eye; they were then softened in a fire, and the eye punched out by hand with a small punch and hammer; the heads were then trimmed off with a file, and the cavity on each side also filed out. But the modern process is as follows.

Modern process.

The wire when drawn to a proper size, which is ascertained by gauges, is made up into coils for package; these coils of wire are heated to a dull red heat in a furnace, and suffered to cool gradually, to soften and

Mechanical Processes.

anneal it, with a view of facilitating the working of the steel; this commences by cutting the wire into lengths, which is done by a pair of shears. The workman being seated before a bench takes, perhaps, a hundred pieces of wire for fine needles, and introduces their ends between the blades, which he opens with his right hand, and presses the ends of the wire against the gauge, which renders them all one length; he cuts them off, and they drop down into a tin pan placed on a small shelf in front of the bench; the ends of the wire are now pressed against the gauge and cut off again. In this way the wires are cut into lengths of the required needles. The second operation is flattening the end for the eye of the needle, which is done by a workman taking three or four pieces of the wire between his finger and thumb, placing them on a small anvil, and striking one blow upon each expands the end sufficiently to receive the point of the punch which pierces the eye. This the same person does before he lays them down with a small instrument fixed on the same block as that to which the anvil is fixed. The end of the needle is placed in a small notch in the bed of the instrument and is put exactly beneath the punch, a slight stroke of the hammer punches the eye, and at the same time forms the semicircular groove near the eye of the needle to bury the thread. The notch which receives the needle is made in a piece of steel which fits into a dove-tail notch in the bed of the instrument, so that it can be changed for a larger or smaller, correspondent to the size of the needles to be pierced. The workman holds the needles in the same manner as he did for flattening, and, placing them one by one successively in the notch in the bed-piece, pierces them by striking a single blow of his hammer on the end of a slider; the slider is immediately returned by a spring. He now places the next needle under the punch, and when they are all pierced in this manner he rolls them over by moving his thumb so as to turn them all half round and bring them upwards, the opposite to that side which was pierced; this being done, he repeats the punching on the other side, with a view to finish and clear the eye and to form the groove which there is in all needles. They are now rounded at the eye end to take off the roughness, which is done in an instant by applying them to a grindstone.

The next process is hardening and tempering. The first is done by placing a great number together upon a piece of iron, bent up at the ends and sides that they may not roll off, and introducing them into a small furnace; when they become of a red heat, they are taken out and suddenly plunged into a vessel of cold water; this renders them very hard. Some manufacturers make use of oil, or tallow, and other ingredients instead of water, which substances are supposed to improve the process. The needles thus hardened are returned to the furnace with the oil upon them, and remain there till the oil inflames, when they are withdrawn and again cooled with cold water. This second process tempers them; at first they were quite hard, and so brittle as to break with the slightest touch; the tempering takes off the brittleness, but leaves them hard enough to take a good point. When they are hardened in water according to the old method, the heat for tempering them can only be guessed at or estimated by experience; but the flaming of the oil is a much more certain method. The needles are now examined, and many of them will be found crooked by hardening,

Manufac-
tures.

which are discovered by rolling them over as they lay in rows on a board, and such are selected and made straight by a blow in the notch in the anvil. Being thus straightened they require to be pointed, which is done by a large grindstone turned by a mill either of water or steam. In this operation the workman, sitting astride before the stone on a block shaped like a saddle, takes up twenty or thirty needles, laid side by side across a small wooden ruler covered with soft leather, another similar ruler being laid over the needles to confine them; he then holds the rulers in his hands, and thus presenting the ends of the needles to the grindstone points them with great dexterity. This operation has been found extremely injurious to the individuals employed, and a method for correcting or alleviating this evil is described at the end of this section. After pointing, they are polished by rolling them in emery powder and olive oil. The points are next finished and rendered perfectly sharp by grinding them upon a wooden wheel covered with emery, being held in the same manner as for the first grinding. They are then cleaned and packed up in certain numbers according to their sizes, and a great number of small packets are made into large parcels, wrapped in several thicknesses of paper, and coverings of bladder and packing-cloth, in which state they are sent to market.

Surgeons'
needles.

(955.) Surgeons' needles are generally made crooked and their points triangular; however, they are of different forms and sizes, and bear different names, according to the purposes they are used for. The largest are needles for amputation; the next kind for wounds; the finest needles are for sutures. They have others very short and flat for tendons; others still shorter, and the eye placed in the middle, for the tying together of vessels, &c. Needles for couching cataracts are of various kinds, all of which have a small, broad, and sharp point or tongue, and some with a sulcus at the point. Surgeons have sometimes used two needles in this operation; one with a sharp point for perforating the coat of the eye, and another with a more obtuse point for depressing or couching the opaque crystalline lens; but care should be taken in the use of any of these that they be first well polished with cloth or leather before they are applied.

(956.) We shall close this short notice with an account of a patent invention for the manufacture of needles of all sorts by Mr. William Bell of Walsall, which we shall give in his own words.

Bell's
Patent.

"The method by which I make needles, bodkins, fish-hooks, knitting-pins, netting-needles, and sail-needles, is by casting them with steel or common fusible iron, called pig or cast iron, into moulds or flasks made with fine sand; or, otherwise, I make the stock or moulds of iron or steel, or any other composition capable of being made into moulds, on which stocks or moulds I sink, engrave, or stamp impressions of the said articles. Into these I pour my melted iron or steel, (I prefer for my purpose sand casting,) and prepare my iron or steel as follows: I melt it in a pot or crucible, in small quantities about the weight of twelve pounds, (and upwards, to twenty pounds,) the more conveniently to divest it of its heterogeneous particles, and to purify it from its earthy or sulphureous qualities. When the iron has attained a proper heat, I take charcoal dust mixed with lime or common salt, which I throw into the pot of melted iron; and by frequently stirring it with an iron rod I bring to the surface of the iron a scoria, which I

frequently skim off, and thus bring my iron into a refined state; I then pour it into the mould before described. The articles being thus formed are capable of being softened, hardened, or tempered in the usual way, by which needles and sail-needles have heretofore been manufactured; therefore the principal merit of my invention is in casting them, instead of making them in the usual way."

(957.) *Needle and other dry grinding.*—In the preceding part of this section we have alluded to the injurious effect of needle grinding upon the health of the individuals, very few of whom are said to reach more than the age of forty, from constantly inhaling the dust thrown off from the needle points and from the grindstone. This evil attracted the attention of the managers of the Society of Arts, who in consequence offered a premium to any person who should propose some remedy for this evil, and accordingly several propositions were made and rewarded; but the most approved was one by Mr. J. H. Abraham of Sheffield, which is as follows: fig. 6, 7, 8, Pl. lxviii. are a section and a back elevation of a needle grinder's wheel, in which *a* is the wheel, *b b* the trams on which it is mounted, *c c* cross rails framed between the trams, *d* the grinder's seat supported on a bracket, *e* an iron guard, which protects the grinder in the event of the stone breaking, and *f* the needles being ground.

It is proposed to protect the workman from the iron and grit-dust which he produces and inhales, by suspending from the ceiling of the grinding room a sheet of canvass, (painted or not,) which shall extend from wall to wall immediately over the axis of the stones. This canvass is to reach to the floor, and is to have two vertical cuts in it from the bottom upwards at each wheel, and the slip of canvass thus partially disengaged is to be turned upwards and made to fasten at various heights, either by a hook or button to accommodate the various diameters of the wheels which may be employed; *g g g' g'* represents the canvass, the line at *g' g'* pointing out a division in it by which the workman gets through to his work; this opening is afterwards secured by buttons or hooks; *h* is the slip cut out to admit the stone, turned up and buttoned at *h'*, leaving an opening about one inch and a half high over the stone, through which the iron and grit-dust is violently impelled by the centrifugal force, as described by the dotted lines *i*, fig. 6. The stream of dust generally maintains a state of brilliant ignition, and moves in the direction of the tangent with extreme velocity for at least twelve inches from the points of the needles; there is therefore no difficulty in conveying by far the larger portion of it into that part of the building separated from the workman by the canvass, and the current produced through the aperture by the revolution of the stone will effectually prevent its return. A few, however, of the lighter particles rise almost perpendicularly from the points of the needles, and these it is proposed to arrest by one or more rows of octangular magnets suspended nearly over the points of the needles, as *k k*, &c.; they may be fixed to a bar *l*, resting and capable of moving up and down on two uprights *m m*, supported either on the trams *b b*, or secured to the iron grate *e*. The canvass, besides the apertures already described, will require some cutting and adapting, to fit as nearly as possible the irregularities of the trams, &c.; but all this will be quite obvious and must depend on the particular construction of the mill to which it is applied. A wooden partition might be used with perfect success instead of the canvass but

Mechanical
Processes.

Dry grind-
ing.

Pl. lxviii.
Fig. 6, 7, 8.

Manufac-
tures.

from the circumstance that the trams and stones are moved forward, as the bands which impel them are shortened by rejoining after having broken, and the pliability of the canvass screen renders it peculiarly fitted for adapting itself to this change of place; but a slight attention to the mode of uniting the bands would make a wooden partition perfectly applicable.

The apparatus described in the engraving has been partially used at Redditch, and, as the testimonials show, has been proved to be effectual. The principal difficulties which oppose its general and successful adoption arise from the nature of the buildings in which the work is performed, and from the habits of the men employed in them. In a building about twenty feet long, not so many high, and nine or ten feet wide, from six to nine men work; they are placed on three stages or shelves about six or seven feet wide, occupying one end of the building; the other end contains the machinery. The men sit close to the end of the wall, and are essentially all in one room, or rather worse than they would be in one room where all worked on the same floor, for the stages are scarcely far enough apart to allow a man to stand upright, and the dust falls through the joints from one to another. These grinding houses are sometimes built in pairs, and in consequence of this a strong side wind, which would otherwise be useful, merely blows the dust from the windward to the leeward house. Added to all this, the use of water as a power acting on overshot wheels occasions the mills to be erected in situations where they are shut up on three sides by banks nearly as high as their roofs. The result of the whole is, that the air is nearly stagnant, that the immense quantity of iron and grit dust hourly produced rolls slowly about the rooms till the atmosphere has become so fully impregnated that the men are scarcely visible on entering at the door; it then begins to be deposited on the floors and timbers, from which it is again disturbed by the motion of the machinery. On each side of the building, in a line with the axles of the wheels, are windows which it is impossible to close in the severest weather, and it frequently happens that the water in which the needles are dipped will freeze on the hands of the workmen. It will be requisite, therefore, for the full success of Mr. Abraham's contrivances that a greater space be left between the workmen and the wall behind, otherwise the canvass partition confines them in a space so small that in summer it attains a temperature almost suffocating. It will also be advantageous that the window be divided into two portions, the division corresponding with the canvass partition. The part next the workmen should have a glazed casement, to be shut when the weather requires it, while the other part might be permanently open.

Although it is true that some of the pointing mills are not subjected to all the defects of construction and situation which have been enumerated, they are without any exception confined in space and ill ventilated. It will be evident, therefore, that the complete reformation of the mischief must depend upon measures to be taken by the larger needle-makers themselves. The benevolent and persevering exertions of Mr. Abraham must be seconded by them to have any sensible effect. If the early production of a lingering disease, and its consequence, a premature death, among a whole class of men, be evils worth remedying, there is no case which calls so loudly for interference as that of the needle

grinders'. Nor is the sacrifice of health and life the only nor perhaps the greatest evil. The workmen are necessarily allured to their pernicious employment by high wages, which produce their almost universal accompaniment, idle and dissolute habits. The excessive earnings of the needle pointers at Redditch maintain a succession of men who taint the whole neighbourhood with profligacy; who with the most perfect consciousness devote themselves to an early death for the sake of a life of idleness and debauchery; and who acquire such a callous indifference to the fate which they know awaits them, that their apprehensions are said to have been excited lest Mr. Abraham's invention should be successful enough to affect their wages.

The case of the dry grinders at Sheffield and other places, though not so appalling as that of the needle-grinders, is sufficiently bad. They work in rooms which are, generally speaking, much better ventilated, and under circumstances which admit of a very simple mode of preventing the dissipation of the dust in the air. Fig. 8 represents a section of a Sheffield grinder's wheel, in which *a* is the wheel which runs in a cast iron trough *b b*; the grinder sits on the block *c*, which lies on the edges of the trough, and holds the article to be ground at *d*, the stream of iron and grit-dust taking the direction *d e*. To retain this dust a piece of canvass *f f*, formed so as to embrace rather more than a quadrant of the wheel, is suspended from the board *g*, which lies loosely on the trough; the board is notched round the wheel, and over the opening three canes or hazel twigs *h h h* are bent, forming an arch to support a canvass hood. The board *g* is easily lifted from its place for the purpose of wetting the canvass, (which must be kept damp,) and is as easily returned when that is done. In this manner the whole of the dust is arrested by some part of the canvass, and being retained there by the moisture requires only to be occasionally shaken out. For further security, an arrangement of magnets may be fixed in a semicircular frame, and this frame may be placed at the opening into the canvass hood, or in any other place which the peculiar circumstances of the case might dictate to the workman. In addition to the radiant magnets, other intermediate ones may also be fixed on the face of the semicircle. In all these cases octagonal magnets are recommended in preference to round or square ones, because the particles of iron seem to obey the magnetic influence with more force at the angles of the bar than at its surface. The magnets should be forged of steel bars about a quarter of an inch square, the attractive power not appearing to reside above a tenth or an eighth of an inch within the surface.

For the protection of the workman against the small quantity of dust which, in spite of every precaution, will float about the rooms, and especially during the operation of raising the stone, when the ordinary apparatus will not apply, Mr. Abraham constructed a muzzle formed of a frame of wood, the upper and lower pieces made circular to fit the lips; on this are fixed two or three thicknesses of crape or muslin, and it is studded with sixteen magnets, which will arrest a considerable portion of the deleterious matter before it can reach the crape; to the upper part of the wooden frame is attached a bent wire, to which crape is fixed for the purpose of protecting the nostrils. The whole is fastened by two strings passing round the head and tying behind. It has also been found that a semicircular frame, but without feet, having the magnets only on the face, may be

Pin-making.

Pin manu-
facture.

(958.) The manufacture of pins is carried on to a very considerable extent in this Country, not only for home consumption, but also for exportation, the English pin being greatly esteemed in all parts of the Continent. Pins formed of brass wire seem to have been unknown in England till about the middle of the XVth Century, before which time they were larger than the present pin and made of box wood, bone, ivory, and some few of silver. In 1543, however, the manufacture of brass pins had become sufficiently important to claim the attention of the Legislature, an Act having been passed in that year, by which it was enacted "that no person shall put to sale any pins, but only such as shall be double-headed and have the head soldered fast to the shank, the pins well smoothed, and the shank well sharpened." Gloucestershire is noted for the number of its pin manufactories. They were first introduced into that County in 1626, by John Tilsby, and it is said that at this time they employ 1500 hands, and send up to the metropolis upwards of £20,000 worth of pins annually. The wire as received at the manufactory is too large for being immediately formed into pins; therefore we may state that drawing the wire to its proper size for the different kinds of pins is the first operation. The wire being thus reduced to its proper dimensions is straightened, and subsequently cut in proper lengths, and again afterwards cut into smaller ones, each length being sufficient for making several pins. Each end of these pieces is pointed so as to be sharp enough for penetrating, without difficulty, through linen, paper, &c., by either men or boys, seated before two small grinding-stones or steel mills, turned by a wheel, either by means of machinery or by the hand. These stones or steel mills are used for making the rough points and for smoothing them, and therefore they are careful to turn the wire so as to render the points uniform and regular. The pin is afterwards cut off to the length that is wanted from each end, and the process is repeated till the whole of the length is pointed.

The manufacture of the head is performed by the following operations: a piece of wire suitable for heads is spun on another piece, whereby the inside wire occasions the upper wire to be hollow when drawn off; this is then in a state required for being cut into heads, which is done by shears, every two rounds of the wire making a single head. The next process is that of heading the lengths; this is done by the operators or work-people taking up a single length and thrusting it among the heads, thereby catching one on, and then immediately placing it under a heavy weight or hammer, when receiving the necessary blow it is made secure, and thus the pin is completed in the first state. After this it is to be blanchéd or whitened, which is accomplished by putting the pin in a copper containing tin and the lees of wine. When this is completed, the pin is in a state for sale.

One great point aimed at in the manufacture of pins has always been so to fix the head on the shank or shaft that it shall remain on firm; but very frequently this object is not attained, either the head will come off at the end, or will descend down the shaft, and in either case the pin becomes useless; to remedy this evil, several Patents have been taken out, either with a

view to a more firm attachment of the wire head, or to raise the head on the wire itself, of which the latter has been the most successful; a very great proportion of pins now in use being of this kind.

Mechanical
Processes.

With a view to the former object a Patent was taken out by Mr. Bundy in 1809, which is thus described. The operation is performed by means of a frame or stock made of metal, in which are fitted a pair of steel dies in the manner of those generally used in the manufacture of screws, held together by cylinders; the dimensions may be various, according to the quality of the work, but the dies most generally in use are about two inches long and one inch wide. In the prominent parts, and that side of each of the two dies which come in contact when in use, are made corresponding grooves, which when pressed together form holes, each to be the diameter of the shaft intended to have the head fixed on; these holes may be made tapering upwards, or contracted at that part close under the head, where half a hemisphere whose diameter is that of the size of the head required is to be worked out.

The dies thus worked are fixed in a particular kind of frame, and placed in the position in which they are while introducing the pointed shafts, each having a head loosely put on. The upper die being at liberty in the frame, the pressure of its weight will be found sufficient to hold the number of shafts with their heads in their respective places, while they are pushed forward with a straight motion till the quantity of the heads prevents the shafts from going any further. In this state it is necessary to turn a lever, to which is fixed a screw for the purpose of forcing the dies together, which holds the shafts firm enough to receive a stroke from a press on the top piece, to secure and form the whole number of heads in the dies. The hemispheres are finished according to fancy, as respects the ornament or figure of moulding intended for the top of the head, by sinking them accordingly. The patentee says, "I leave a point in the centre of those cavities in the top piece, which serves when forced into the top of the shaft to widen it there and form a rivet, and thereby secure the head firm from coming off the top of the shaft; and, the dies being hard screwed together with the lever, there will be a collar formed by that pressure on the shaft under the head sufficient to prevent the liability of the head being by any ordinary means forced down the shaft." Having described the working parts and explained the process by drawings, Mr. Bundy adds, that, placing the whole in a fly-press, one stroke therewith on the top piece will be found sufficient to complete the whole number of heads in the dies. "Hitherto," it is observed, "it has been the practice to strike the head several times, but my method of effectually and securely fastening the heads on the shafts and leaving the heads of a superior form, is by placing the shafts in a perpendicular direction, and striking the heads and shafts on the tops, which I call superior heads, and which method I claim as my invention. To succeed in the completest manner in forming these superior heads, it will be necessary that the dimensions of the heads before they are fixed to the shafts should be particularly attended to. If they are to be of nearly a spherical figure, they should be prepared of a greater depth of axis than the diameter, that the diameter may be small enough to go freely into the hemispheres in the dies and top piece which are to receive them; for this purpose, head wire may be made flat, either by drawing or rolling to a size

Manufac-
tures.

such that when spun one or more rounds will be sufficient for a head. I recommend head wire of a smaller size than ordinary without flattening, so that when spun and cut, three rounds of it shall contain the quantity of metal required for the size of the intended head. When the heads have been fixed on the shafts by the fly-press, the screw is then to be turned back by a lever, and taking hold of the milled head, which is on the head of the small shaft, and which goes through the screw, and is fixed to the top dies by being screwed hard in the die, it may be drawn back to separate the dies sufficiently wide for the superior headed pins which they contain to fall through into some place prepared to receive them."

In 1824, a Patent was taken out by Mr. Wright of Wellclose-square, in which several improvements are proposed to be effected, *viz.*, first, in the method of supplying the wire for making the pins, and of straightening the wire as it advances; secondly, in the method of cutting the wire into suitable lengths for forming the pins; thirdly, in the method of carrying the wire so cut to be pointed and headed; fourthly, in the apparatus for pointing the wire; and, lastly, in the manner of forming or raising the head at one end thereof by means of two dies, by which the head of the pin is formed of a portion of the same piece of wire as the shaft or shank of the pin itself. The machinery and apparatus by which all these operations are performed are exceedingly ingenious, but they require too many figures for us to allow ourselves to describe them; we must, therefore, refer the curious reader to vol. liii. of the *Repertory of Arts*, where he will find the specification at length, with accurate engravings of the several machines, dies, &c. Whatever method or machinery is employed in forming the pin, it is when finished, as far as the making is concerned, still brass; it is then thrown into a copper containing a solution of tin and lees of wine, where it remains some time, but when taken out it assumes a white but very dull appearance; to give it a polish, it is put into a tub containing a quantity of bran, which is set in motion by turning a shaft that runs through its centre, and thus by means of friction it becomes perfectly bright. The pin being complete, it only remains to separate it from the bran, which is performed by a sort of winnowing, the bran flying off and leaving the pin behind.

Pins are sometimes made of iron wire, rendered black by a varnish of linseed oil with lamp black, which are designed for the dress of persons in mourning; they, however, are at present but little in use, having been superseded by steel pins rendered a deep purple by tempering.

A more general account of pin-making will be found in our Introduction.

Plating and Plated Goods.

Former
method of
plating.

(959.) The old method of plating was to apply thin silver leaves over brass articles after they were in other respects completely finished, and is still known by the term French plating; and some English manufactured goods, particularly those on steel, are plated in this manner; such, for example, as plated dessert knives and other articles for the table. Thus, for instance, the knife being first properly formed in steel, a piece of silver leaf is cut to cover the knife on each side; it is then placed for a short time at the entrance of the plating furnace, during which the union of the silver

and steel is completely effected, and it only remains to give to it its proper burnish. With brass goods the polishing is first produced on the original article, they are then rendered free from grease and every other extraneous matter, and the part to be plated is heated to a temperature just below that which causes a change of colour in the metal, leaf-silver is then laid upon the part, and while hot is rubbed with a steel burnisher perfectly dry and clean. By this means the silver was made to adhere to the brass, which from the action of the burnisher assumed a fine polish. The goods thus plated differ but little in appearance from those plated according to the present method, but they possess less permanency, and this old practice is almost entirely laid aside by English platers, except in the cases above referred to.

Mechanical
Processes.

According to the present practice, the metal is first produced in sheets plated on one or both sides, and the goods are manufactured at once in the plated form. The first process consists in casting an ingot of alloy of copper and brass, generally about one and one-eighth of an inch in thickness, three inches broad and eighteen inches long. Great precaution is required in this process to obtain a very perfect ingot, for any holes or other imperfections will produce a general defect in the plate after rolling. The ingot is cast in cast-iron moulds, having rising mouth-pieces to give a certain pressure to the metal, and to allow any impurities to rise above the general surface, and considerable skill is required to have the heat of the mould and that of the metal properly adjusted.

Modern
method of
plating.

The ingot being thus formed is next to be plated, in order to which the face of it must be very carefully dressed with a file till it is entirely free from any unevenness or imperfection. When the plate is to be silvered on both sides, these must of course be both dressed in the same manner; the former is called single, the latter double plating, and in both cases the greatest accuracy is required, such indeed that either surface will bear to be examined by a considerable magnifying power without exhibiting imperfection. The thickness of the silver to be laid upon the copper is generally such that its weight is about one-twenty-fourth or one-thirtieth that of the copper, and of course about one-twelfth or one-fifteenth when plated on both sides, the proportional thickness of the two metals varying in the single plating from one-thirty-sixth to one-fortieth.

The plate of silver is cut a little less than the size of the copper surface, made flat, and scraped perfectly clean; the copper surface being equally clean they are laid together, and the silver plate is tied down with wire. A little saturated solution of borax is now introduced under the edge of the silver plate on every side, which fuses at a low red heat and prevents the oxygen of the atmosphere from affecting the surface of the copper, which would injure the adhesion of the silver, and in this state the ingot is brought to the plating furnace. This has a grate on a level with the bottom of the door; the fuel consists of coke, and the ingot is laid on the coke and the door shut. When the ingot has attained nearly a proper heat, the plater watches the process carefully through a hole in the furnace door, and knowing by certain signs when the proper state is attained, it is quickly removed; for, if allowed to remain longer, the silver would become alloyed with the copper and the plate spoiled as far as relates to its intended purpose. In this process the silver is, in fact, soldered to the copper,

Manufac-
tures.

although no solder is expressly employed. It is well known to chemists that an alloy of silver and copper, as well as many other alloys, is more fusible than either of the simple metals; and, from what takes place in the above process, it will be easily inferred that a portion of silver and copper unite at the contiguous surfaces, which, fusing before the silver or the copper, unites the former with the latter. The ingot being now plated is made perfectly clean, and is ready to be rolled. The first rollers employed for plated metal are of cast iron, similar in size and construction to those employed for sheet iron and sheet copper. The metal is rolled cold and annealed from time to time; when it has gone through the rollers a certain number of times, it acquires such a degree of hardness that the rollers have not much effect, and if the rolling were continued the metal would crack. This is an evil which must be remedied by taking the metal to a reverberatory furnace; where it is laid upon a hearth of brick or fire-stone, and the flame of coal made to pass over it, but, since the metal is required to be slowly brought to a dull red, the heat is not intense. It may now be cooled in the quickest way possible to save time, as quenching in water does not affect it as is the case with steel; it is now passed through rollers as before till it becomes hard, and then annealed and rolled again till it is reduced something short of the size required; this being done, it is again annealed and passed through a pair of rollers faced with cased steel and finely polished, which gives the surface great smoothness and truth. It is now annealed for the last time, and the sheets, after having been immersed in hot dilute sulphuric acid, are then scoured with fine Calais sand, which fits them for the workman to shape into different articles.

The pieces of metal to be plated for the purpose of making wire are forged out of bar copper unalloyed, which pieces are of a cylindrical shape, about eighteen or twenty inches long, and about one and a quarter inch in diameter. The true cylindrical shape is given to the copper by wiredrawing; it is then made perfectly clean and metallic by scraping, but the silver to be laid upon it is much thinner in proportion to the copper than was stated in the sheet metal; the silver is first formed into a tube, one edge projecting a little over the other, and the copper cylinder is a little less in diameter than the tube, and so much longer as to admit one end to project. The tube is now slipped upon it with the seam upwards, and a steel burnisher, with rounded polished edges and a handle at each end, is rubbed briskly backwards and forwards upon the over-lapped edges of silver, at the same time using considerable pressure; by this means the surfaces are completely welded together, so that it would be difficult to find where the union had taken place. The cylinder of copper intended to be plated is made perfectly clean; the same caution is necessary for the inside of the silver tube; it is now to be put upon the cylinder, which is about two inches longer than the tube; there is a small groove made round the cylinders coinciding with the ends of the silver tube; into this groove the ends of the tube are closely worked so as to render the space between the tube and the cylinder perfectly air tight. The necessity of this is obvious, since the whole is required to be heated red hot, which would cause the oxidation of the copper and prevent the silver from adhering to it. When the cylinder and tube are together heated slightly red hot, the same burnisher used for uniting the tube is

now rubbed briskly over the tube in a longitudinal direction. This unites the silver firmly to the copper, and makes it fit for drawing into wire of various forms and sizes: the machine employed for drawing this wire is precisely similar to that used for brass and copper wire. The great variety of figure and form given to it depends upon the plate through which it is drawn, some of which are flat, half round, fluted, or with mouldings; it is chiefly used for making bread-baskets, toast-racks, snuff-boxes, and many other articles requiring much neatness and elegance with little manual labour. The wire after drawing, like sheets after rolling, is annealed, and afterwards cleaned with hot dilute sulphuric acid.

(960.) The plate and wire being prepared as above described, we come now to the manufacture of the plated articles, which resemble in a great measure that of thin copper articles, but being commonly of a lighter description admit of and require more delicate processes. The workers in plated goods are termed braziers, candlestick-makers, and pierce-makers; the former being employed in making the larger articles, the second in making candlesticks and similar goods, and the latter the open work, such as bread-baskets, tea-trays, &c. Formerly all the different shaped vessels were made with the hammer, but at present all but the very largest are raised or sunk by the stamping hammer, except, indeed, some of the smaller parts, as in the forming of candlesticks, &c., and these are formed by a lathe, the pattern attached to the mandril being of the intended form of the part. A circular plate of the metal of the proper size being placed on the front of the mandril, the workman applies to it a hard wooden tool and, pressing it back upon the mandril, at length brings out the form and figure of the part required. By much the larger proportion of goods, however, are raised by the stamping hammer. This consists of a large stone base on which is secured an iron anvil, and to the latter the die containing the figure of the intended article is fixed by four screws; see fig. 9, 10, plate lxviii. The manner of working the hammer is by the workman placing his foot in the stirrup shown in fig. 10, and seizing at the same time the rope with his hand; the weight by the action of both is raised to the proper height, and is then left to descend with its whole force. The figures require but little description: *a, a*, fig. 9, are two upright square pillars with the angles opposed to each other, which work in angular recesses in the hammer *d*, which admits the latter to work freely and truly from top to bottom, the weight being first raised by pulling on the rope as above described.

All moderate-sized vessels are raised in this manner, but the larger kind by the hand hammer, and those which are of less diameter at the top and bottom than in the middle must necessarily be either raised by hand or stamped in two pieces, and afterwards soldered in the middle. The dies should be made of cast steel, but it should be in such state as to weld with iron, so that the iron should not be much below the surface of the die; this is more particularly requisite when the die is to be hardened; in other cases the whole die may be of cast steel. The die being placed on the anvil, and the metal cut into pieces of proper size, the top of the die is surrounded with a paste made of oil and clay an inch or two above the surface, and into this cavity is poured a proper quantity of melted lead, which of course receives an impression of the die reversed. The under side of the stamping hammer has a flat face of iron fitted into it, about the breadth and length of the die, which is

Stamping
hammer.

Description
of the dies.

Manufac-
tures.

called the *licker-up*, and when the lead becomes solid, the hammer is raised to a certain height and let fall upon it; the under side of the piece of iron above named being cut on the surface into teeth, in shape like those of a rasp, firmly adheres to the lead, and the latter is then raised with the hammer. The metal to be stamped is now placed over the die, and the hammer with the lead is made to fall on it till the impression is completed. If, however, the vessel is of any considerable depth, two or three dies are used, one bigger than another, the last being the proper size and shape of the vessel.

This process of stamping hammer and dies is employed in forming not only plated vessels, but also livery buttons and medals; many beautiful specimens of the latter kind are exhibited at Sir E. Tomason's manufactory at Birmingham, where the process above described is shown to any stranger having permission to view the establishment.

Cylindrical and conical vessels are mostly formed by bending and soldering: the bending is performed on blocks of wood with wooden hammers, and in the smaller articles, such as the ornamental parts of candlesticks, it is done on a mandril, as has been already stated, the several successive parts forming the entire candlestick being soldered to each other, the number of such pieces in the most ornamented articles of this kind amounting to upwards of thirty. The ornamental beadings and mouldings, seen in many plated articles, are formed by passing strips of the metal through rollers fluted to form different patterns, or by means of what are called swages, by which the metal is made to take up its proper figure.

Silver
edges.

A very great improvement in the manufacture of all plated goods is the introduction of silver edges, beads, and mouldings, for before this means of defending the prominent parts was introduced, the article soon became naked of plating in those parts, and the nature of the interior was discovered, and consequently its beauty destroyed; but by this practice the edges, beads, and prominent parts will now remain perfect longer than the more protected plated divisions. The silver employed for this purpose is rolled extremely thin, a superficial inch sometimes not weighing more than ten or twelve grains. This is of course too delicate to have its ornamental figures given by the processes above described for beads and mouldings, it is therefore done by lead and dies as described in stamping, but of course by more gentle means.

When these silver mouldings are formed, and the refuse metal is removed, they are laid upon a level plate with the hollow side uppermost, and small pieces of rosin are put into the hollow parts and soft solder melted in with the soldering iron. To prevent the solder adhering accidentally to the outer surface, it is previously covered with a composition of size and whitening of about the consistence of paint; the solder, which is very soft, is composed of equal parts of lead and tin. The silver shells thus filled with soft solder will now admit of being bent into almost any form, and after they are accurately fitted to the place they are intended to occupy, the part being first made clean and partially tinned, they only require to be secured by temporary fastenings till the parts can be exposed to a degree of heat capable of melting the solder.

When the different plated goods come from the hands of the workman, the metal, although clean, is of a dull white colour, possessing no polish whatever. The last

finish has therefore still to be given, and is generally performed by women in separate apartments. The bur-
nishing tools are generally blood stone, but some are of
hardened steel finely polished. The latter are for bur-
nishing the minute parts which cannot be touched with
the blood stones, these being commonly used only on
the larger and more open parts.

Mechanical
Processes.

Small Shot Manufacture.

(961.) This, like most other mechanical processes, has undergone considerable alteration within a short time. The general process consists in melting the lead, and after stirring and taking the scum from its surface, throwing upon the the same a certain quantity of powdered yellow orpiment, then the whole being well stirred the orpiment will flame, and to now judge whether he metal is in a proper state it is tested by dropping a little of it into a glass of water, and if the particles or shot turn out to be round and without tails it is in a proper state, if not more orpiment must be added. The next process is to take a copper plate hollowed towards the middle, punched through with several holes according to the size of the intended shot, which is placed in a frame over a vessel of water. This plate is kept to a proper temperature by means which differ in different manufactories, and on the plate is poured a certain quantity of melted lead, which makes its way through the holes in the bottom and falls into the water in round drops. The shot thus made are dried over a gentle fire, always stirring them to prevent their melting and adhering together; they are then sorted according to their different sizes, and put up in separate bags, differently numbered, for sale. The uniformity in the figure of the shot is greatly promoted by lengthening the fall of the drops, which in some modern establishments is very considerable, whereas in the old method the lead did not fall more than a few inches.

Tinning.

(962.) The affinity which has place between tin and
some other metals, particularly iron, copper, and brass,
renders the process of tinning a subject of considerable
importance in the Arts and Manufactures of this Coun-
try. Iron is a metal greatly disposed to oxidation, but
by being covered with a thin coating of tin its surface
is preserved from the action of the atmosphere, and the
articles formed of it are greatly preserved, particularly
those used for culinary purposes. Again, copper and
brass, when thus employed, are liable to oxidation, not so
injurious to the metal, perhaps, as dangerous from their
poisonous effects to individuals, which are supposed
also to be prevented by a slight coating of tin given to
the inside of the vessels.

Tinning.

Tinning iron plates.—The art and practice of tin-
ning thin iron plates was derived by us from the
Germans, being very little known in England till the
early part of the last century, when the attention of the
English artists was called to the subject by Mr. Rutty,
in a Paper published in the *Philosophical Transactions*
for 1725. An attempt had certainly been made in 1681
to introduce the practice by Andrew Yarranton, which,
however, failed; but the former was more successful,
and the Art is now perhaps better known and more skill-
fully executed in this Country than in any other, and it
is moreover carried on to such extent as to render it an
important branch of English manufacture.

Tinning
iron plates.

Manufac-
tures.

French
process.

Although the processes described by Mr. Rutty are now in many respects changed, his description will not on that account be less interesting to the curious reader. The author observes, that the making of tin plates, called in France *fer blanc*, or white iron, properly begins with preparing the leaves or plates of iron to be tinned which are supposed to be sufficiently thin and flat and cut into squares; but those are the most proper which, when heated, are easily extensible and yet can be forged with the hammer, the most soft and extremely flexible, as well as the more brittle, being rejected. These leaves are drawn from bars of iron about an inch square, which being made a little flat are cut into thin pieces, then folded together, and being made into parcels containing forty leaves each, are beaten all at once with a hammer of 600 to 700 pounds weight. After this the principal part of the whole Art is to prepare these leaves, for the lightest dust or the least rust on their surface will prevent the tin from uniting with them. This is taken off by steeping the plates in acid waters for a certain time, and then scouring them with sand. By this method a woman may clean more plates in an hour than the most expeditious workman can file in many days.

Of these waters the author mentions several, but what the Germans themselves used, and which they made a great secret of, he found to be only common water made slightly acid with rye, which requires very little pains; for after they have ground the grain roughly and pounded it, they leave it to ferment in common water for a certain time, and with a little patience they are sure to have an acid menstruum. With this they fill troughs or tuns into which they put piles of plates; and to produce the acidity the better and to have more activity, the vessels are kept in vaults or stoves which have little air, and in which lighted charcoal is kept. The workmen go into these vaults once or twice a day, either to turn the plates that they may be equally exposed to the action of the acid liquor, or to take out those that are sufficiently cleansed, or to put others into their place; and as the liquor is more acid, or the heat of the vault or stove is more intense, the plates are sooner cleansed, but this process requires at least two days, and sometimes a great deal more.

This is the method which the Germans, employed in the tin-works in France, made use of, to prepare the iron plates to receive the coat of tin; but, as the author observed that the constant attendance on them in the stoves was very laborious, the heat therein being almost insupportable to those who are not used to it, he proposes some other methods which are attended with very little trouble, and as small, if not a less, expense, and which on trial succeeded full as well. Having, therefore, observed that the iron leaves or plates are covered with scale or layer, half vitrified by the fire, on which acids have none or very little effect, he imagined that, instead of dissolving the iron in these acid waters, it would be better to make it rust and thereby put it in a condition to be easier cleansed from these scales; as rust is accompanied with a sort of fermentation and rarefaction, and the matter which rusts takes up a greater space and raises up whatever opposes it. To this purpose he steeped iron plates in different acid menstrooms, as in water in which alum, common salt, and sal ammoniac were separately dissolved, and others of the same iron he only dipped into the same waters, and instantly taking them out exposed them to

the air. These latter were rusted by all of them, but sooner by that in which the sal-ammoniac was dissolved. After two days, during which every plate had been dipped into the menstruum but twice or thrice, he scoured them and likewise those he had left to steep for that time, and, comparing them together, found that those which had been only wetted at different times cleansed better than those which were steeped, the rust covering all the surface of the latter without raising the scale, whereas in the former, as soon as one part of the metal is detached, it is attracted by the menstruum and the surface is raised into blisters of rust.

These dissolvents, the author observes, though weak in themselves, yet produce the effect as well as the stronger, which are much dearer; but among the latter he prefers vinegar, which, being very plentiful in France, may be used with little cost, for it is only necessary to dip each leaf into it and take it out again immediately; leaving it afterwards in some moist place, it will be scaled in forty-eight hours, if care be taken to repeat this three or four times a day. The scaling will be still more expeditious by dissolving a little sal-ammoniac in the vinegar, a pound or two to a puncheon, for as the vinegar dissolves iron well, so sal-ammoniac rusts it sooner than any other salt; but this must be used very moderately, and the leaf must be left to steep in clean water, to dissolve any particles of it that may stick to its surface, which may otherwise make it rust after it is tinned. If vinegar is used for scaling, and it should be desirable to do it at a less expense, it is only necessary to plunge the leaves once or twice at furthest, and when the vinegar is dried on the surface, it should either be sprinkled with water or the leaves dipped into it and taken out immediately. There are several other ways of making iron rust; as keeping it in a moist cellar, exposing it to the dew, sprinkling it with common water several times in a day, which will still act quicker by dissolving sal-ammoniac in it. In those Countries where pyrites are common, the vitriolic waters will scale them soon enough, which are almost as cheap as common water; it is only necessary to heap pyrites together and to leave them to moulder in the air, and to make afterwards a lixivium with them and common water, which, forming a lie, will have the desired effect. But as the leaves of iron are much more easily cleansed on one side than on the other, the bad side rarely taking the brilliant polish in the tinning, but having always some spots, which happens because in the beating, one side is more exposed to the action of the hammer and is therefore better plained, the author again advises not to steep them, but only to moisten them in order to make them rust, moistening that side only that wants it most; whereas if they are steeped, as the bad side will take double or triple the time of the other, the acid menstruum will dissolve the surface and occasion a loss of iron. He next gives two cautions necessary to be followed: the first is in the management of the plates before they come to be prepared, which is, in the beating of them, to change the place of each in its turn that every one may receive the immediate action of the hammer, otherwise they will not extend; the second is to steep them in clay or fuller's earth tempered with water, before beating them, to prevent their soldering with each other. He then closes this part of the operation with remarking that, whichever of these methods is adopted, whether the old one, of which he has learned the secret, or any of the new, which he has here shown, it is absolutely necessary

Mechanical
Processes.

Manufac-
tures.

after the plates are sufficiently scaled to scour them with sand, and when no more black spots remain on their surface to throw them into water to prevent their rusting again, and leave them in it till the instant they are to be tinned or blanched, as it is called. This, he observes, is the very object of the whole Art, and is kept as much a secret by the blancher as the acid corroding menstruum is by the scalers; but the manner of doing it is thus: they flux the tin in a large iron crucible which has the figure of a pyramid frustum with four faces, of which the two opposite ones are less than the others. This crucible they heat only from below, its upper border being luted in the furnace quite round. The depth of the crucible always exceeds the length of the plates to be tinned, which are always put in downright, and the tin ought to swim over them.

For this purpose, artificers of various trades prepare the plates in different manners, which are all exceptionable; but the Germans, he perceived, made use of no preparation whatever, except putting the scouring plates into clean water as just remarked, but when the tin is melted in the crucible it is covered with a layer of a sort of suet an inch or two thick, through which the plate must pass before it comes to the tin, the first use of which is to keep the tin from burning, and if any part should take fire, as the suet will soon moisten it, to reduce it to its natural state again. This suet is a composition, as the blanchers say, and is of a black colour, which the author thought might be given it with soot or the smoke of a chimney, only to spread a mystery over their work; but he found it true so far, that common unprepared suet was not sufficient, for after several attempts there was always something wanting to render the success of the operation certain. The whole secret, then, of blanching lies entirely in the preparation of this suet; and this he at last discovered to consist only in first frying and burning it, which not only gives it the colour, but puts it into a condition to give the iron a disposition to be tinned, which it does very successfully.

The tin itself ought to have a certain degree of heat, for if it be not hot enough, it will not adhere to the iron, if too hot, it will cover it with too thin a coat, and the plates will have several colours, as a mixture of red, blue, and yellow, and the whole will appear of a bad yellow cast. To prevent this, by knowing when the tin has a proper degree of heat, they might first make an essay with small pieces of the scaled plates, their appearance would show when the tin was in proper order; but, generally speaking, the plates are dipped into tin that is more or less hot, according to the thickness the coat is required to be. Some plates only require one layer, these are plunged into tin that has a less degree of heat than that in which those plates are dipped which are to have two layers; when the second layer is given, they are put into tin that has not so great a degree of heat as that into which they were put the first time, besides which, it is to be observed that the tin, which is to give the second coat, ought to be fresh covered with suet, but only with the common sort without preparation; for melted tin is sufficiently disposed to attach itself to solid tin, and in this case it is to tin itself to which the new tin is to be joined. *Philosophical Transactions*, 1725.

Process in
England
and Wales.

(963.) The present process as carried on in South Wales is described by Mr. Donovan in his *Descriptive Excursions through South Wales* in 1805, and it differs

but little from the operation which the author has seen in Staffordshire and in other Counties. Mechanical Processes.

The iron ore employed in this manufacture is the common kind of the country, intermixed with a large portion of the fine hæmatite from Ulverstone in Lancashire, which gives a very fine metal. This too is smelted with charcoal instead of coke, to produce a metal of the greatest purity and extensibility and closeness of texture, which qualities are particularly required in this manufacture. The reduced ore is smelted in the usual manner and cast into pigs, which are then wrought by the hammer into long flat bars, that are afterwards cut into pieces of about ten inches in length. These are then wrought into plates by being heated red hot, and passed through a flattening-mill, which consists of two large cylinders of steel, casehardened, and secured in a frame of iron. These are placed contiguously to each other, but with a certain interval of space, and revolve in a contrary direction, so that when one end of the bar is thrust in the space between the cylinders, the whole is drawn through and proportionably extended and flattened in the passage. The distance between the cylinders, which of course determines the thickness of the plate, is maintained and regulated by screws which can be altered at pleasure. When the bar is thus made into a plate of twice the thickness of the ordinary plates, it is heated red hot, cut in two by a pair of shears and one piece folded exactly over the other, and both repassed repeatedly through the cylinders till the folded plate has extended to the same length and breadth as the plate was before cutting. It is then clipped round the edges and the two plates are torn asunder, (which requires some little force,) after which they are finished by passing through a finer rolling-press, so as to take away every increase or inequality in the plate; and those that are too rough to pass through this finer press are thrown aside.

The plates are then steeped in a very weak acid liquor, and when taken out are scoured thoroughly with bran, so as to be quite bright and polished to enable the tin to adhere. The tin is melted in deep rectangular crucibles, and kept fluid by a moderate charcoal fire beneath. To prevent its calcination, a quantity of grease prepared from lintseed oil and suet is constantly kept floating on the surface of the tin, and renewed as it evaporates off, which gives an excessive nauseous stench. The plate is then taken up by one corner with a pair of pincers, and dipped vertically into the tin, and when withdrawn is found beautifully white and resplendent with the coating of this metal that adheres to it. This dipping is repeated three times for what is called *single tin plate*, and six times for the *double plate*. The plates are then cleansed and sorted, and are fit for use.

The following process is for tinning without acids, a recent French Patent.

(964.) The iron plates, flattened or hammered, are scoured and cleansed in a large wooden vessel containing ten pounds of rye-flour to one hundred pounds of water: it is left to ferment until the scaly portion which is found upon the surface of the plate has wholly separated; that being accomplished, a bath of the tinning material is prepared in the following manner. To eighty pounds of fine tin are added twelve pounds of beef and as many of mutton fat, which latter are previously melted in a copper till the whole twenty-four pounds are reduced to half their weight; this is poured into the melted tin, after which half an ounce of fine silver is added and the whole is melted together. Tinning without acids.

Manufactures.

The mode of tinning.—The scoured sheets are dipped into a solution of half an ounce of sal-ammoniac to three pounds of water, after which they are plunged quickly and frequently into the bath of tinning composition already prepared in the caldron, care being taken to scrape the places not perfectly tinned: after these precautions, the sheets are drained and dried, having been previously shaken for the purpose of cleaning off the superabundant composition which would otherwise cling to the edges and ends of the sheets of pipe. The above composition is of tried solidity, and may be easily extended over surfaces of any length.

The length of the iron sheets intended for tinning may be seven feet, and the width in any proportion: with regard to pipes of the same length in a single piece, they may be soldered with copper, a far more solid soldering than brass, and which does not make any thickness or ridge.

Tinning tacks, nails, &c.

(965.) *Tinning tacks, nails, and other small articles.*—The workman having previously made the surfaces of the articles clean from rust or other oxide by pickling them, or putting them into sulphuric, muriatic, or nitric acid, diluted with water, as usual, and washing them well afterwards in water, he puts them in a stone gallon bottle, having an oval body, a narrow neck, and a handle to lift it by, together with a proportionate quantity of grain tin and of sal-ammoniac. He then places the vessel, lying upon its side, over a charcoal fire made upon a forge hearth and heats it, continually turning it round all the while, and frequently shaking it to distribute the tin uniformly over the surfaces of the articles to be tinned. They are then thrown into water to wash away all remains of the sal-ammoniac, and finally dried in saw-dust made warm.

The great merit of this process consists in the employment of the *stoneware vessel*, which not only prevents the dissipation of the sal-ammoniac in fumes, but also gives up the whole of the tin to the articles to be tinned, which would not be the case were a metallic vessel to be used.

Wiredrawing.

History of Art.

(966.) This very ingenious process, according to Beckmann, had its origin some time in the XIVth Century, prior to which time all the wire that was used was probably produced by means of the hammer, anvil, and file, of which he gives several instances. Our business here is, however, only with wiredrawing, by means of iron or steel plates, an Art which was first apparently introduced into Germany about the middle of the XIVth Century, for Beckmann observes that before that time the manufacturers of wire were called wire-smiths, but afterwards wire-drawers or wire-millers. Beckmann is much enraptured with the Art of wiredrawing; he observes that the greatest improvement ever made in this Art was undoubtedly the invention of the large drawing machine driven by water, and in which the axletree, by means of a lever, moves a pair of pincers that open as they fall against the drawing plate, lay hold of the wire which is guided through a hole in the plate, shut as they are drawn back, and in that manner pull the wire along with them. What a pity, he exclaims, that neither the inventor, nor the time when the machine was invented, is known! it is however more than probable that it was first constructed at Nuremberg, by a person named Rudolf, who long kept it a secret, and by these

means acquired a considerable fortune. Conrade Celter, who wrote about the year 1471, is the only author known at present who confirms this information; and he tells us that the son of the inventor, seduced by avaricious people, discovered to them the whole secret of the machinery, which so incensed the father that he would have put him to death had he not saved himself by flight.

Mechanical Processes.

"This Art," the author further observes, "was brought to great perfection at Nuremberg. Several improvements were from time to time found out by different persons who turned them to their advantage, and who received exclusive Patents for using them, sometimes from the Emperor, and sometimes from the council, which gave occasion for many tedious lawsuits." We have, however, reason to believe that the finer kinds of work, particularly in gold and silver, were carried on with great success above all in France and Italy, and that many improvements were brought from these Countries to Germany. In another part it is stated that all the wire manufactured in England, till the year 1565, was hand drawn, and that the art of employing mills was about that time introduced by foreigners. "Before that time the English wire was bad, and the greater part of the iron wire used in the Kingdom, as well as the instruments employed by the woolcombers, was brought from foreign Countries. According to some accounts, however, this Art was carried to England at a much later period, for we are told the first wire-making was established at Esher by J. Mommer and D. Demetrius; and Anderson says that a Dutchman constructed at Sheen, near Richmond, in 1663, the first flatting-mill ever seen in England."

At all events the Art of wiredrawing has since been carried to a great degree of perfection in England, particularly that part of it which is employed in the manufactures. Of this an immense quantity is used in card-making for the woollen and cloth manufactures; we have mentioned one establishment only, under Card-making, Mr. Dyers' of Manchester, in which more than thirty miles of wire is drawn and manufactured into cards every day, at least when the establishment is in complete operation. The French, however, appear still to be superior to the English in drawing the wires for piano-forte strings and other musical instruments.

(967.) The process commonly employed in this Country is exceedingly simple, the apparatus consisting only of a draw plate and draw bench. The draw plate is a thick plate of the finest steel perforated with holes of various sizes, from that of the largest to that of the smallest wire required. These holes are punched in the plate while hot, by well-pointed punches of German steel, four heats are generally required, and at every heat a finer punch is used, so as to make the hole taper, or take a slightly conical form; these holes are made to differ from each other by nearly imperceptible gradations.

Draw plate.

The draw bench is a simple machine, consisting of a horizontal roller or axis turned by four vertical levers like a rolling press, a strong chain or strap is coiled round the roller, and at the end of the strap is a pair of pincers for taking hold of the end of the piece of metal to be drawn; the draw plate is then made to bear against two strong iron pins placed in the draw bench, and the piece of metal being passed through the proper hole is seized by the pincers. By turning the levers the pincers at the end of the strap pull the piece of metal through the hole in the draw

Draw bench.

Manufac-
ture.

plate, and thus lengthen it a certain quantity; it is then drawn through smaller and smaller holes, being annealed when necessary, till it is reduced to the size required. This is a very general description, but it must be obvious that there is some difference between the early and the finishing process; in the former the wire is too stout to be coiled as it is passed through the plate, but in the latter stages it is as easily coiled as a thread of silk or cotton, and is so coiled in the English manufactures; in the former case the pincers are placed on a movable frame which recedes from the draw plate; moreover in this case seldom more than one wire is drawn at a time, but after it is reduced to the smaller size several such wires are drawn at the same time. The different coils to be drawn are placed on one side of the drawing frame or bench on reels; the ends are passed through the plates to the other side, where they are conducted to a cylinder or roller, which being made to revolve by steam, or other power, the process is continued with six, eight, or more wires till the reels are empty.

In wiredrawing much depends upon the annealing and other treatment of the wire; the smaller iron wire is previous to drawing immersed in a liquid formed of water and ale grounds, which is said greatly to facilitate the process; but we believe different manufacturers have different processes, which are not made public, and on which the character of the wire in some measure depends.

M. Pleyel's
Patent.

(968.) The following is the description of a process protected by a Patent for fifteen years for drawing wire for pianofortes and other musical instruments by M. Pleyel, an ingenious mechanic in Paris, and is thus described in vol. iv. of the *Repertory of Arts*.

"The white wires are made from soft and very ductile wire. The French iron wire best suited for this purpose are the kinds known under the name of *for de roche*. We employ in this manufacture only iron which has already been reduced into wire, at least to the dimension of two-thirds of a line in diameter. These wires owe their quality to the manner of tempering or annealing the iron wire, and of passing it through the draw plates.

"To anneal the wire, a fire-place is built of bricks and mortar, of a cylindrical form, having its exterior and interior edges furnished with an iron hoop beneath a large chimney. The dimensions of this fire-place or furnace are proportioned to the quantity of iron wire intended to be annealed at one time, which is placed in it upon an iron grate. This grate is placed so high as not to allow the fire to touch the wire. The furnace is covered with a sheet iron cover in which there is a hole for allowing the smoke to escape. The iron wire is placed in coils upon the grate till it reaches to about four inches of the top, the cover is put on, and a fire lighted with white wood only. The heat is kept up till the wire has acquired a pale red colour, and not more. That the fire may be distributed equally throughout, the cover should be frequently turned, because the hole in it would attract the heat, and without that precaution one side would be heated more than another. This method of annealing suits only iron wire of the size of one-third of a line in diameter; to draw it finer, the following process should be employed.

"In the furnace already mentioned, at a certain height above the grate, are supports on which another similar grate is placed. A strong plate of sheet iron is laid on each of these grates; the dimensions of the

plates allowing an inch all round for the passage of the ascending smoke, to allow the cylinder to fall from the top and to promote an equal communication of heat. The iron wire ought to be wound into a narrower space than the width of the plates of sheet iron, and placed on the lower plate in such quantity as to reach the upper one; the lower fire-place is filled with fuel, and the same combustible is placed on the upper plate; both fires are then lighted, the cover is put on and frequently turned during the process.

"In a furnace capable of holding fifty pounds of iron wire the fire is kept up for four or five hours, the length of time depending, however, on the situation of the furnace and consumption of fuel. The first process of annealing is commonly done twice on the same iron wire; the second is done after that wire has been drawn three or four times through the draw plates for reducing its diameter. The second process is employed but once.

(969.) "*Tools used in this manufacture.*—These tools consist of, first, a wooden work bench four or five feet long and three wide; secondly, a plank three feet long, one foot wide, and three inches thick, which is fixed to one of the edges of the bench by two pins. Above this plank two little barrels of wood are raised, ten inches in length and six in diameter, each having its axis placed in the direction of the width of the plank, and received in two brass supports, fixed firmly against the lateral sides of the same plank. The axis of each roller is furnished with a handle for moving it. At the middle of the plank there is raised, to the height of the centre of the axis of the barrels, a piece of wood of the whole width of the plank, in which is a groove four or five lines deep. At each extremity of this piece of wood two wooden uprights are framed, supporting a cross-piece in which is a second groove corresponding to the first. A draw plate is adjusted so as to slide easily between these two grooves. At each end of the same plank, and by the side of the draw plate, a small piece of hard wood is placed, on which the ends of the iron wire are filed before passing them through the plates.

"A sort of reel nearly like those used for thread, excepting that it is conical, serves to receive the rings of iron wire intended to be drawn. The bench serving as a foot for this reel is raised to the height of the barrels. On a small wooden upright, placed in a mortise made in the plank between the barrel and the draw plate, a little box is fixed, containing grease composed of lard and tallow. There is a hole through this box to allow the iron wire to pass through it and become smeared with the grease. To beat up the draw plate when the holes are too much worn, and to pierce it, we employ a block of wood similar to those intended for receiving small anvils, and on which a mortise is made sufficiently deep. A small file is used to reduce the end of the wire when beginning to draw; a pair of flat pincers for drawing it when introduced, into the holes of the draw plate; a common hammer and an iron gauge for measuring the sizes of wire; lastly, a draw plate is the most essential tool that we must have for this work. The material of which this tool is composed and the way in which it is pierced contribute very much to the quality of the wires.

"A draw plate, to be a good one, must be made of a substance neither too hard nor too soft, and those which are steeled are good for nothing, and pure iron is equally unsuitable. The best material for making them is a mixture of the best bar iron and cast iron,

Mechanical
Processes.

Tools used
in the
process.

Manufactures.

These plates should be pierced so that every hole goes on diminishing in diameter underneath; these holes are commenced with conical steel punches which are struck; the draw plate is then put to heat in a fire of only wood, and the operation of piercing it is afterwards completed when cold with steel punches. It is necessary to have punches corresponding to all the diameters of wires required to be drawn.

Manner of working.

(970.) "*Manner of working.*—When all the tools are ready, as above mentioned, and the iron wire also prepared, it is put upon a reel which is placed at the end of the bench. The end of the wire is then filed, pushed through the grease box, and into the hole of the draw plate corresponding to its size, and is drawn by hand with the pincers till it can be attached to the barrel, where it is fastened by points which are fixed for that purpose on the barrel, the barrel is then turned gently by means of its handle.

"For the first course it is necessary that the barrel which does not act should be removed, because it would be in the way of the wire coming off the reel to enter the draw plate. When the whole wire has passed through one hole, the other barrel is put into its place, the wire is sharpened anew, the draw plate is turned, the wire passed through the next following hole in size, drawn with the pincers, and fixed to the second barrel which is turned by its handle, so that the wire unwinds from the first barrel, passes through the draw plate, and winds on the second. It is necessary to take care that the wire be always passed through the grease box before entering the hole in the draw plate. One thing essential to be observed is that the wire passes through holes corresponding to its size so as to require but little power to pull it through, consequently the diameter of the wire is reduced but a very small quantity each time it passes through a hole in the plate.

"To draw wire of two-thirds of a line in diameter to one-third of a line, it is necessary to anneal it twice; brought to this size, it is annealed by the method before described, and afterwards it will not require annealing to be reduced to the greatest degree of fineness. In order that the iron wire may possess the proper degree of ductility and tenacity to form a sonorous string, it must pass five or six times through the draw plate after the last annealing. When the iron wire is reduced to the desired size, nothing more is requisite than to give it the necessary polish and white colour that it may render clear and distinct sounds.

Polishing.

"*Polishing and whitening of the wires.*—When the wire is drawn down to the proper size the draw plate and grease box are removed, the wire is fastened to the vacant barrel, and wound upon it, making it glide at the same time through a piece of leather previously rubbed on rotten stone. It is frequently necessary to repeat this operation to obtain a fine polish. The method of winding the wire on bobbins it is needless to describe. The size of the bobbins depends on the number desired to the pound weight.

Yellow wires.

"*Yellow Wires.*—The implements necessary for making these are the same as for the white wires, and they are used in the same manner, the only difference is in the polishing and annealing. To obtain good yellow wire we must employ only brass, (*mitraille jaune*), and three-tenths of calamine. This brass should be of a pure yellow colour; it may be procured at the manufactories in rods of a line in diameter. It is to be annealed once by heating it in the furnace, placing it on the grate, put-

ting white wood above and below it to obtain a clear and gentle fire. It is to be heated for an hour or two so as to be only red hot. On taking it out it should be dipped for a moment into a boiler of hot tallow. It is afterwards allowed to cool completely, and is then passed through the draw plate in the way already described for white wire.

Mechanical Processes.

"The brass wire is polished by the process before mentioned, excepting that instead of rotten stone we employ red tripoli; strings or wires made by these methods will stand in tune a tone and a half higher than the wires of Nuremberg." *Repertory of Arts*, No. 55.

MECHANICAL PROCESSES EMPLOYED IN THE MANUFACTURE OF FIBROUS MATERIALS.

Cotton Manufacture.

(971.) The extent and importance of the cotton manufactures of Great Britain, and the extraordinary increase which has taken place in them within a comparatively short period, naturally call for a more detailed account than we have been able to bestow upon other branches. The rapid extension of the cotton trade will be seen by a statement made by Edw. Baines, jun. Esq., in his excellent *History of the Cotton Manufactures in Great Britain*, i. e., that sixty years since our manufacturers consumed little more than 3,000,000 pounds of raw cotton annually, whereas the annual consumption now is 280,000,000 pounds. In 1750, the County of Lancaster, the chief seat of the trade, had a population of only 297,400, and in 1831 the number of its inhabitants was 1,336,854; and a similar increase has taken place in Lanarkshire, the principal seat of this manufacture in Scotland. The families supported by this trade are estimated by the same author to amount to 1,500,000 individuals, and the goods produced to furnish not only a large part of the clothing consumed in this Country, but also to supply nearly one-half of the immense export trade of Great Britain, finding their way into almost all the markets of the world.

Introductory remarks.

Early History of Cotton Manufactures.

Our object will be principally to illustrate the state of the cotton manufactures of Great Britain; but it will be interesting first to take a rapid sketch of its early history amongst other nations, and to trace it thence in its progress step by step, till it is found triumphantly established and extended in our own Country. There seems little doubt that the original birth-place of the cotton manufacture was in India, where it flourished long before the time to which any authentic history extends. That cloths made of wool, flax, or linen and silk, are of very ancient date, is sufficiently shown both by sacred and profane Historians, but in no one of these early Works have we any reference to goods manufactured from cotton, yet it is highly probable that cotton was woven in India as early as the earliest of the cloths above alluded to in Egypt. Herodotus, who wrote about the year 445 B. C., shows clearly that cotton was then and had probably been for ages the customary wear of the Indians; for in speaking of these people he says, they possessed a kind of plant which instead of fruit produces wool of a finer and better quality than that of sheep, of which the Indians make their cloths. If, then, Mr. Baines remarks,

Early history of the cotton manufactures.

Manufac-
tures.

cottons were the common clothing of the people, it may with strong probability be inferred that they had been so for centuries, as the most striking characteristic of these people is their extreme indisposition to change; and it is to be remarked that Herodotus mentions this plant, and the manufacture produced from it, as peculiar to India; he makes no reference to vegetable wool being made into clothing elsewhere. Of the Babylonians he says distinctly, that their dress was of linen and wool, and that of the Egyptians of linen only, except that the priests wore a white woollen shawl when not engaged in their ministrations; it may, therefore, be concluded with certainty that at this time the cotton manufacture prevailed generally in India, and that it existed in no other Country West of the Indus.

We are led to the same conclusion by the statement of Nearchus, the Admiral employed to descend the Indus (327 B. C.) and to navigate the coast of Persia to the river Tigris. And from the interesting and obviously faithful narrative of this observant navigator, we learn that the Indians wore linen garments, the substance of which they were made growing on trees, which, he remarks, is indeed flax, or rather something much whiter and finer than flax. They wear shirts of the same which reach down to the middle of their legs, and veils which cover their heads and a great part of their shoulders; the name of the tree with the Indians, he says, was *tala*, and he describes its pods. Strabo also, who died A. D. 25, alludes to Indian cotton goods, and states that in his own time the cotton tree grew and cloths were manufactured from its produce in Susiana, a Province of Persia at the head of the Persian Gulf.

This valuable plant was now obviously advancing Westward, for in the time of Pliny, who lived about fifty years later than Strabo, the cotton plant was known in Upper Egypt, and also in the Island of Tylos, in the Persian Gulf. He says, "In Upper Egypt, towards Arabia, there grows a shrub, which some call *gossypium* and others *xylon*, from which the stuffs are made which we call *xylina*. It is small and bears a fruit resembling the filbert, within which is a downy wool which is spun into thread. There is nothing to be preferred to these stuffs for whiteness or softness, and beautiful cloths are made of them for the Priests of Egypt." The same author, in his description of the Island of Tylos, enumerates amongst its remarkable productions "wool-bearing trees, with leaves exactly like those of the vine but smaller, bearing a fruit like a gourd and of the size of a quince, which, bursting when it is ripe, displays a ball of downy wool, from which are made costly garments resembling linen."

We shall conclude this first period of our history of the cotton manufacture by a quotation from Mr. Baines's Work above mentioned, and to which we have been largely indebted for much valuable information.

"The first mention of cottons as an article of trade, is in that valuable record of ancient commerce, *The Circumnavigation of the Erythræan Sea, Periplus Maris Erythræi*, by Arrian, an Egyptian Greek, who lived in the Ist or IId Century of the Christian Era. This writer, who was himself a merchant and a navigator, sailed round the coasts of the Erythræan Sea, which comprehends that part of the ocean from the Red Sea to the furthest extremity of India; and he particularly describes the imports and exports of several Indian towns, in their trade with the Arabs and Greeks. From

this Work it appears that the Arab traders brought Indian cottons to Aduli, a port of the Red Sea; that the ports beyond the Red Sea had an established trade with Patala, (on the Indus,) Ariakè, and Barygaza, (the modern Baroche, on the great river Nerbuddah, near the North-Western coast of India,) and received from them, among other things, cotton goods of various kinds; that Barygaza exported largely the calicoes, muslins, and other cottons, both plain and ornamented with flowers, made in the Provinces of which this was the port, and in the interior and more remote Provinces of India; that Masalia (the modern Masulipatam) was then, as it has been ever since, famous for the manufacture of cotton piece goods; and that the muslins of Bengal were then, as at the present day, superior to all others, and received from the Greeks the name of *Gangitiki*, indicating that they were made on the borders of the Ganges.

"From the evidence of Strabo, Pliny, and the *Periplus*, quoted above, it appears that the growth and manufacture of cotton had, at the Christian Era, extended to Persia and Egypt, including muslins and calicoes, both plain and figured, which were brought by Greek navigators to the ports of Egypt and Arabia, whence, it may presumed, they would reach the Capital of the Roman world, and some of the wealthy cities of Greece. Yet cotton goods could not have been imported into Rome or Greece to any considerable extent, or even regularly, since there is no distinct mention of them as articles of importation or consumption by any of the writers of those Countries, though the other produce of the East, gold, spices, precious stones, and even silks, are often specified. The same conclusion is still more decisively drawn from the fact that the various kinds of cotton goods are not enumerated in the Roman law *De Publicanis et Vectigalibus*, which included the different articles of merchandise imported, with the duties chargeable upon them. But as a very extensive trading intercourse existed between Italy and Egypt, it is certain that cotton goods would have been imported into Italy if they had been largely manufactured in Egypt. It is probable that the use of cotton clothing was introduced very slowly in that Country, and did not become general for some centuries.

"To those who have observed the rapid spread of the cotton manufacture in the present generation, it may appear beyond measure extraordinary that a branch of industry so apt to propagate itself should have lingered thirteen hundred years on the coast of the Mediterranean before it crossed that sea into Greece or Italy. It may also appear remarkable, that the exquisite fabrics of India should not, when known, have been eagerly desired in the Roman Empire, and been largely imported. Such was the case with silks, which, though more costly, and fetched from the more remote region of China, were sought with avidity by the ladies of Rome, and still more by those of the Eastern Capital, Constantinople. Silk, both raw and manufactured, became an important article of commerce through India and Persia, and even by the route of the Oxus, the Caspian, and the Volga; and it is justly commemorated as an important event, that silk-worms, with the art of manufacturing their produce, were brought from China to Constantinople by two Persian Monks in the reign of Justinian, A. D. 552. It appears that Indian cotton goods were imported into the Eastern Empire in the same Age, as they are in the list of goods charged with duties in

Mechanical
Processes.

Manufac-
tures.

Justinian's digest of the laws; but being scarcely mentioned by any writers, whilst silks are perpetually mentioned, it must be inferred that cottons were held in very subordinate estimation, and probably introduced only in small quantities. Left to conjecture to account for this fact, I can only suppose that the soft texture, glossy surface, and brilliant hues of silk, so different from woollen, linen, or cotton, and so much superior, captivated general admiration; and that muslins and chintzes could not vie with silks as articles of luxury, whilst they were too dear to compete with the manufactures of wool and flax as the materials of ordinary wear."

It would be inconsistent with the limited space within which we must confine the present historical sketch to extend our remarks to greater length respecting the progress of the cultivation of this plant, and the manufactures from it in different parts of Arabia, Africa, and Asia; it will be sufficient to state that, about the XIIIth Century, the use of it for clothing had become rather common with the Moors and Arabians, through whom it was introduced into Spain and Italy, its manufacture, however, being principally confined to the former Country.

The cotton
manufac-
ture of the
Americans
on the first
discovery of
that Con-
tinent.

(972.) The next period in the history of cotton, both as regards its growth and manufacture, is connected with the discovery of America, where both the cotton tree was found cultivated and cotton cloths were richly manufactured. Cottons formed the principal article of clothing amongst the Mexicans, as they had neither hemp nor silk, nor had they wool except that of rabbits, and the flax which they did possess was not used by them for articles of clothing; their only materials for making cloths, besides cotton, were feathers, the wool of rabbits and hares, and a fibrous plant called the maguei. Amongst the presents sent by Cortes, the conqueror of Mexico, to the Emperor Charles V. were cotton mantles of various colours, waistcoats, handkerchiefs, counterpanes, tapestries, and carpets. The Mexicans also used cotton in making paper, and their warriors wore cuirasses of cotton which covered the body from the neck to the waist. Columbus also found the cotton-tree growing wild and in great abundance in Hispaniola and other West India islands, and on the Continent of South America, where the inhabitants wore cotton dresses and made their fishing-nets of the same material. When Magellan went out on his circumnavigation of the Globe in 1591, the Brazilians were accustomed to make their beds of this vegetable down, so that it cannot be doubted that the cotton as well as the indigo plant are indigenous in America as well as in India; their art of manufacture is also, in all probability, equally original, and it is impossible to say it is not as ancient.

Cultivation
in Europe.

With respect to the cultivation of the cotton plant, it has never made much progress in Europe, the climate generally being unsuited to it; it was, however, in the time of the Moors, introduced into Spain and has been cultivated in Italy. But henceforth our inquiries will apply principally to its manufacture and its general progress as an article of commerce.

Cotton
manufac-
tured in
Spain.

(973.) It appears that as early as the Xth Century cotton was manufactured in many parts of Spain, particularly in Cordova, Grenada, and Seville; and Barcelona, in the XIIIth Century, was celebrated for its cotton cloths; here the cotton was prepared and spun for the weaving of various stuffs used in those times, but principally for the manufacture of cotton sail-cloth, which was always a considerable branch of industry in that

mercantile city, which for more than five hundred years was the station of the Spanish squadrons. The same city was famous for its fustians, also a strong kind of fabric used to line garments, which derives its name from the Spanish word *fuste*, which signifies substance.

Mechanical
Processes.

The first record of the cotton manufacture in Italy does not seem to point to an earlier date than the beginning of the XIVth Century, and it is doubtful whether even then it was more than half cotton and half linen, the former constituting the weft and the latter the warp, as they were first made on their introduction into this Country; the same may also be said of the manufactures of Germany and Flanders, where they had, as is observed in the Work above quoted, "a lingering and ignoble existence." It would be altogether a mistake, it is further observed, to suppose that the same manufacture ever existed in any other part of Europe which now exists in England. A coarse and heavy article was indeed fabricated, probably half cotton and half linen, but it was of too little importance to attract the notice of historians; but calicoes, muslins, and the more delicate cotton goods were never made in Europe, except, possibly, by the Moors in the South of Spain, until the invention of the spinning machinery in England.

In Italy and
Germany.

(974.) There is some uncertainty respecting the time at which the cotton manufacture first found its way into this Country, or at least some misunderstanding formerly existed on this point, in consequence of the fabrics made at Manchester and some other towns in Lancashire being denominated for some reason cottons, which were actually woollen or linen. How this misnomer occurred it is difficult to determine; some have thought that cotton at that day was only a corruption of coating; at all events the cottons mentioned by the parties alluded to were not made of that material. The first historical notice we meet with is in the *Itinerary of Leland*, who visited Lancashire in the reign of Henry VIII. "Bolton-upon-Moore market," says he, "standeth most by cottons; divers villages in the moores about Bolton do make cottons." From this an inference has been drawn in favour of the existence of the manufacture of cotton in Lancashire at this early period; a supposition which is however completely overturned by an Act passed the 5th and 6th of Edward VI., 1552, entitled, "for the true making of woollen cloth;" in which it is ordered that all the cottons called Manchester, Lancashire, and Cheshire cottons, full wrought to the sale, shall be in length full twenty-two yards, and contain in breadth three-quarters of a yard in the water, and shall weigh thirty pounds in the piece at least. Also, that all other cloths called Manchester rugs, otherwise named Manchester friezes, full wrought for sale, shall contain in length thirty-six yards, and in breadth three-quarters of a yard, coming out of the water, and shall not be stretched on the tenter or otherwise about a nail of a yard in breadth, and, being so fully wrought and well dried, shall weigh every piece forty-eight pounds at the least. However paradoxical it may appear, it is nevertheless clear from this passage of the Act, that the Manchester cottons of that day were a species of woollen cloth, and that of the coarsest and strongest kind, as is sufficiently proved by the weight required by the Statute. The testimony of Camden also to this point is decisive. When speaking of Manchester in 1590, he says, "This town excels the towns immediately around it in handsomeness, populousness, woollen manufactures, market-

First intro-
duction
into Eng-
land.

Manufac-
tures.

place, church and college, but did much more excel them in the last age, as well by the glory of its woollen cloths, which they call *Manchester cottons*, as by the privilege of sanctuary which the authority of Parliament under Henry VIII. transferred to Chester."

The manufacture of these cottons was known also in Wales, as appears from the eighth of Elizabeth, 1566; in which we have the following historical fact. "In the town of Shrewsbury there hath been, time out of mind of man, and yet is, a company, fraternity, or guild of the art and mystery of drapers, which said fraternity hath, by reason of a certain trade and occupation of buying and selling of Welsh cloth and linen, commonly called *Welsh cottons*, frizes, and plains, which they have had and used amongst them, been able not only to live thereby, but also have, at their common cost, provided houses and other necessities for poor people within the said town of Shrewsbury." The distinction of the Welsh cottons here into frizes and plains is another proof of their being made of wool.

It is certainly singular, that the term cotton should be applied to goods manufactured wholly of wool, and which from their weight and substance could not possibly be intended as imitations of or substitutes for the cotton goods of any other Country.

The fact is, however, sufficiently evident from the preceding quotations, and still further from the consideration that, at the present day, the Kendal cottons, a manufacture which has subsisted now nearly five centuries, are made entirely of wool, and that of the coarsest kind.

Like the Welsh cottons, they are manufactured both frized and plain, and are used chiefly for negro clothing in America and the West Indies, though some are worn at home by the poor or labouring husbandmen. Various conjectures have been offered respecting the origin of the name, but the most probable is, as we have mentioned, that it is a corruption of the word *coating*. However this may be, it is very certain that the Manchester, Cheshire, and Welsh cottons, which in all probability were derived from those of Kendal, were made entirely of wool, and that it is to these goods the observation of Leland applies in the quotation we have before given.

Early im-
portation of
cotton wool.

It appears, therefore, that we have nothing here on which may be fixed the date of the time at which the cotton manufacture was introduced into England, but cotton in the form of wool had been for centuries imported in small quantities, to be used as candle-wicks, as appears by an entry in the books of Bolton Abbey, Yorkshire, where 27s. 1d. is charged for different articles, and, amongst others, cotton for candles.

The next mention of cotton wool imported, according to Mr. Baines, occurs in *The Processe of the Libel of English Policie*, originally published in 1430, and re-published in Hakluyt's *Collection of Early Voyages*, in which, amongst other imported articles, cotton is included.

At the beginning of the XVIth Century the evidences of a regular importation of cotton become more numerous. Hakluyt records that "in the yeeres of our Lord 1511, 1512, and till 1554, diuers tall ships of London, with certaine other ships of Southampton and Bristow, had an ordinary and vsual trade to Sicilia, Cundie, Chio, and somewhiles to Cyprus, as also to Tripolis Barutti in Syria," and, after stating various articles exported, amongst them is named cottons, (no doubt of the woollen kind already noticed,) and amongst the imported articles cotton wool, which, however,

VOL. VIII.

Mechanical
Processes.

it appears, was used for candle-wicks, probably for beds also, and some few other such purposes. The earliest actual record relating to cotton manufacture is in the year 1641, and there is good reason for concluding that it could not have existed very long before that period, or if it did, it was on too inconsiderable a scale to attract the notice either of the legislature or of any author of note, whose works are still extant. The record above referred to is in a work by Lewis Roberts, called *The Treasure of Traffic*, published in 1641, where he says,

"The town of Manchester, in Lanchashire, must be also herein remembered, and worthily for their encouragement commended, who buy the yarn of the Irish in great quantity, and, weaving it, return the same again into Ireland to sell. Neither doth their industry rest here, for they buy *cotton wool* in London, that comes first from Cyprus and Smyrna, and at home worke the same, and perfect it into *fustians*, *vermillions*, *dimities*, and other stufes, and then return it to London, where the same is vented and sold, and not seldom sent into forrain parts, who have means, at far easier termes, to provide themselves of the said first materials." (Original Edition, p. 32, 33.)

The same author further says, "The Levant or Turkey brings in return thereof (*i. e.* of English woollens) great quantity of *cotton* and *cotton yarn*, grogram yarn, and raw silke into England, (which shows the benefit accruing to this kingdom of that Company;) for here the said cloth is first shipped out and exported in its full perfection, dyed and drest, and thereby the prime native commoditie of this kingdom is increased, improved, and vented, and the cotten yarne and raw silk obtained." (p. 34.)

From the above evidence it is manifest that the cotton manufacture had in 1641 become well established at Manchester. It not only supplied the home trade with several kinds of cotton goods, but furnished them as a regular article of exportation from the metropolis to the distant markets of the Levant; and the importation of cotton wool and cotton yarn had also become regular and considerable. Manchester still retained its manufacture of linen, and as linen yarn was used as the warp for fustians, and nearly all other cotton goods in this Country, down to the year 1773, it may be said that the linen manufacture prepared the way for the cotton manufacture, and long continued its auxiliary. It may therefore from all the above facts be regarded as, in a very high degree, probable, that the cotton manufacture was introduced into England towards the close of the XVIth Century, by the Flemish Protestant Emigrants.

This view receives confirmation from a passage in Fuller's *Worthies of England*. Dr. Fuller, who wrote in 1662, in his notice of Humphery Chetham, the celebrated founder of the Blue Coat Hospital and Library at Manchester, who was born in the year 1580, says, "George, Humphery, and Ralph (Chetham) embarked in the trade for which Manchester had been for some time distinguished, the chief branch of which was the manufacture of cottons. Bolton at that period was no less the market for *fustians*, which were brought thither from all parts of the surrounding country. Of these last, especially, the Chethams were the principal buyers, and the London market was chiefly supplied by them with those materials of apparel *then in almost general use throughout the nation*." Humphery Chetham, "when High Sheriffe of this County, 1635, discharged the place with great honour, inasmuch that very

4 T

Manufac-
tures.

good gentlemen, of birth and estate, did wear this cloth at the assize to testify their unfeigned affection to him; and two of them (John Huntley and W. Wrigley, Esqrs.) of the same profession with himself, have since been sheriffs of the county." (vol. i. p. 554.)

This passage shows that fustians were "in almost general use throughout the nation" while the Chethams were in business; and as Humphery Chetham was High Sheriff in 1635, when he was fifty-five years of age, we may conclude that he had then dealt in that article for a number of years. Of course, fustians must have been made in Manchester and Bolton for a considerable time before the publication of Lewis Roberts' book. The spread of the manufacture was afterwards by no means rapid; the same obstacles which impeded its growth in other Countries of Europe impeded it in England. Owing to the rudeness of the spinning machinery, fine yarn could not be spun, and of course fine goods could not be woven. Fustians, dimities, and other strong fabrics were made, but calicoes and the more delicate cotton goods were not attempted.

From *A Description of the Towns of Manchester and Salford*, attached to a plan of the towns, taken about the year 1650, the following information is derived relative to trade: "The trade is not inferior to that of many cities in the kingdom, chiefly consisting in *woolen, frizes, fustians, sack-cloth, mingled-stuffs, caps, inkles, tapes, points, &c.*, whereby not only the better sort of men are employed, but also the very children, by their own labour, can maintain themselves. There are, besides, all kinds of foreign merchandize brought and returned by the merchants of the town, amounting to the sum of many thousands of pounds weekly." Dr. Fuller, whose authority has been already quoted, and whose work was published in 1662, gives some further information concerning the manufactures of Manchester and Bolton. The passage will not be the less acceptable if we preserve the quaint conceits of the old Divine. After mentioning the names of Jen, Augsburg, and Milan fustians, he says, "These retain their old names at this day, though these several sorts are made in this Country, whose inhabitants, buying the *cotton wool* or *yarne* coming from beyond the sea, make it here into fustians, to the good employment of the poor, and great improvement of the rich therein, serving mean people for their outsides, and their betters for the lining of their garments. Bolton is the *staple place* for this commodity, being brought thither from *all parts of the country*."

"As for *Manchester*, the *cottons* thereof carry away the credit in our nation, and so they did a hundred and fifty years agoe. For when learned Leland, on the cost of King Henry the VIIIth, with his guide, travailed Lanchashire, he called Manchester the fairest and quickest town in this country; and sure I am, it hath lost neither spruceness nor spirits since that time. Other commodities made in Manchester are so small in themselves, and various in their kinds, they *will fill the shop of a haberdasher of small wares*. Being, therefore, too many for me to reckon up or remember, it will be the safest way to wrap them all together in some *Manchester ticken*, and to fasten them with the *pinns*, (to prevent their falling out and scattering,) or tye them with the *tape*, and also because sure bind, sure find, to bind them about the *points* and *laces* all made in the same place."

For the above particulars, quotations, references, &c.

we are indebted to the Work of Mr. Baines, which the reader, who wishes for complete information on this interesting subject, will do well to consult. The facts there stated must have been collected with great labour, and are arranged with judgment and perspicuity, and from them we learn that about the year 1697 the cotton trade had increased so much as to export goods to the amount of £5915, and in 1701 to £23,253 sterling, and that in the same years the weight of cotton imported amounted to 2,000,000 pounds.

Cotton Spinning by Machinery.

(975.) We come now to the second period of the history of the cotton manufactures of Great Britain; viz., to the year 1738, from which we may date the origin of many important inventions in both weaving and carding, as well as the first attempt at roller spinning, which was afterwards so successfully pursued by Arkwright, who is indeed very commonly, but not truly, considered as the original inventor of that process.

Up to the period above stated, no better or more dexterous mode of spinning had been practised than by a wheel and spindle, every single thread requiring the undivided attention of one person, and the consequence was, that a sufficient quantity of the cotton twist could not be obtained to answer the demand of the weaver, even at that time, while the necessarily high price of the article when manufactured prevented much increase in the demand. About this time, the advantage and necessity of a more rapid means of producing the cotton yarn led a highly ingenious person (Mr. John Wyatt, of Birmingham) to turn his attention to the subject, in which, as far as skill and contrivance went, he seems to have possessed every requisite qualification, but he was not, as it would appear, so able a negotiator or merchant as mechanic, and to this, and a want, perhaps, of sufficient support, the manufactory which was established by him in partnership with others failed of the success it so well merited. Our business here, however, is not so much with the success of the undertaking, in a pecuniary point of view, as with the original invention, which in other hands, and in more favourable time, has laid the foundation of many private princely fortunes, and raised Great Britain itself to a mercantile eminence never before attained by any nation of either ancient or modern times.

In every mode of spinning, whether the material be cotton, flax, or wool, the objects to be accomplished are to draw out the loose fibres in a regular and continuous line, and, after reducing them to the requisite continuity, to twist them into threads. Previously to the operation of spinning, the cotton is submitted to a process called carding, which will be described as we proceed. This was formerly effected by hand with single cards; these were afterwards made double, but it was still a work performed by hand, and the cotton was stripped off the cards in loose rolls called *cardings* or *slivers*, and the only difference between the slivers produced by the old hand cards and those by the present carding engine, hereafter to be described, is, that the former were in lengths only of a few inches, while the latter are in lengths of some hundred yards. The sliver thus produced has to be rendered considerably more firm before the cotton can be actually submitted to the process of spinning, and this is now generally effected by two or more small pair of rollers placed horizontally, the upper

Processes.

State of the
cotton ma-
nufacture
in 1738.

Wyatt in-
vents
the roller
spinning.

Manufac-
tures.

and lower roller in each pair revolving in contact. The sliver being put between the first pair of rollers, is by their revolution drawn through and compressed; it is then caught by the second pair of rollers, placed immediately in front, which revolve with three, four, or more times the velocity of the first pair, and which accordingly lengthen the sliver and reduce its sectional area in the same proportion; the sliver in some modern machines is still passed through other pairs of rollers acting precisely on the same principle, and is at length, when properly extended and compressed, attached to a spindle and fly, the rapid revolutions of which twist it into a thread, and at the same time wind it upon a bobbin. In order that these rollers may take a proper hold of the cotton to urge it forward, the lower roller is fluted and the upper one covered with leather.

Such is the beautiful and admirable contrivance by which a machine is made to do what was formerly effected by the fingers only, and of which the honour of the discovery (rather than a minute description) is at present the object of our inquiry. That the process has been gradually and greatly improved since the time when the method was first suggested there is abundant evidence, so also is the steam-engine since Watt's first Patent; but the honour of giving to it its present form is due to that able mechanic, and on precisely the same grounds the honour of spinning by rollers is, we conceive, due to Wyatt, although it was his misfortune to become a bankrupt, while the second inventor, Sir R. Arkwright, made a splendid fortune. The evidence of the first invention being due to a period nearly thirty years prior to Arkwright's is shown by the following verbatim copy of the Patent granted to a foreigner, Lewis Paul, for this invention, and which is only witnessed by the actual inventor Wyatt; but other manuscript documents which have been inspected by Mr. Baines, and of which he has given extracts, leave no doubt that, whatever might have been the motive for taking out the Patent in the name of Lewis Paul, John Wyatt was the author of the invention.

(976.) Patent for Spinning by Rollers in 1738.

"Twentieth part of Close Rolls in the Twelfth Year of King George the Second.

Lewis
Paul's first
Patent, the
invention
of Wyatt.

"Lewis Paul's description } TO ALL TO WHOM THESE PRESENTS shall come, Lewis Paul, of Birmingham, in the county of Warwick, gentleman, sendeth greeting. Whereas his present Majesty, by his Royall Letters Patent, under the seal of Great Britain, bearing date the twenty-fourth day of June, in the twelfth year of his reign, hath given and granted unto me, the said Lewis Paul, my executors, administrators, and assigns, sole privilege and authority to make, use, exercise, and vend a new invented machine or engine, for the spinning of wooll and cotton, in a manner entirely new; To have, hold, exercise, and enjoy the said licence, unto me, my executors, administrators, and assigns, for the term of fourteen years, from the date of the said Letters Patent, according to the statute in such case made and provided. In which said Letters Patent is contained a provisal, that if I, the said Lewis Paul, shall not particularly describe and ascertain the nature and form of the said invention, and in what manner the same is to be performed, by an instrument in writing under my hand and seal, and cause the same

to be inrolled in the High Court of Chancery within two calendar months after the date of the said Patent, the same was to be void, as by the said Letters Patent, relation being thereon to be had, may appear. Now know all men by these presents, that I, the said Lewis Paul, do by this present writing, under my hand and seal, declare the nature and form of the said invention to be, and the manner the same is to be performed by, is as follows, to wit. The said machine, engine, or invention will spin wooll or cotton into thread, yarn, or worsted, which, before it is placed therein, must be first prepared in manner following: (to wit:) all those sorts of wooll or cotton, which it is necessary to card, must have each card-full batt, or roll, joined together so as to make the mass become a kind of rope, or thread, of raw wooll. In that sort of wooll which it is necessary to combe, commonly called jarsey, a strict regard must be had to make the slivers of an equal thickness from end to end. The wooll or cotton being thus prepared, one end of the mass, rope, thread, or sliver, is put betwixt a pair of rowlers, cillinders, or cones, or some such movements, which, being twined round by their motion, draws in the raw mass of wooll or cotton to be spun, in proportion to the velocity given to such rowlers, cillinders, or cones; as the prepared mass passes regularly through or betwixt these rowlers, cillinders, or cones, a succession of other rowlers, cillinders, or cones moving proportionary faster than the first, draw the rope, thread, or sliver into any degree of fineness which may be required: sometimes these successive rowlers, cillinders, or cones (but not the first) have another rotation besides that which diminishes the thread, yarn, or worsted, (viz.) that they give it a small degree of twist betwixt each pair, by means of the thread itself passing through the axis and center of that rotation. In some other cases only the first pair of rowlers, cillinders, or cones are used, and then the bobbyn, spole, or quill upon which the thread, yarn, or worsted is spun, is so contrived as to draw faster than the first rowlers, cillinders, or cones give, and in such proportion as the first mass, rope, or sliver is proposed to be diminished. In witness whereof I have hereunto set my hand and seal, the twentieth day of July, in the year of our Lord One Thousand Seven Hundred and Thirty-Eight.

LEWIS PAUL.

"Signed and sealed (being first duly stamped) in the presence of us,

SAMUEL GUY,
JOHN WYATT.

"And be it remembered, that the twentieth day of July, in the year above written, the aforesaid Lewis Paul came before our said Lord the King in his Chancery, and acknowledged the description aforesaid, and all and every thing therein contained and specified, in forme above written, and also the description aforesaid was stampd according to the tenor of the statute made in the sixth year of the reign of the late King and Queen, William and Mary of England and so forth. Inrolled the twentieth day of July, in the year above written.

THOMAS BENNETT.

"This is a true copy from the original record remaining in the Chapel of the Rolls, having been examined.

JOHN KIPLING."

Roller spin-
ning at Bir-
mingham
and North-
ampton.

This important document, although placed amongst the other recorded Patents at the Patent Office, has been only very recently made public in Mr. Baines's Work already referred to: he was furnished with it by Mr. Guest, another able author on the cotton manufactures, but who had not fallen upon it when his last edition was printed. It was known that some such Patent existed, but it having always been sought for in Wyatt's name, the search had hitherto been unsuccessful.

There can, we think, be no longer any doubt concerning the author of this highly ingenious and important invention, and other manuscript documents prove that not only was the Patent then granted, but also that the manufacture of cotton yarn, founded on this process, was carried on at Birmingham in 1741—2, and another at Northampton; there is also proof by a letter from Mr. Wyatt, addressed to Sir Leicester Holt, that he had shared the fate of numerous other ingenious inventors, the letter being from him while a prisoner for debt, requesting Sir Leicester to support a Bill then before Parliament for the relief of insolvents.

The following narrative by Mr. Charles Wyatt, relative to his father's claims, as above stated, will, we trust, be found highly interesting; it is addressed to his brother, then editor and publisher of the *Repertory of Arts*, and is published in the Number of January, 1818. We give it verbatim.

"Bedford-row, Nov. 15, 1817.

Particulars
of Wyatt's
claim by his
son.

(977.) "Dear Brother,—In compliance with your request, I send you some account of the origin of the present method of spinning by machinery, for insertion in the *Repertory of Arts and Manufactures*, which being a receptacle of useful knowledge, nothing can with more propriety fill up a part of its columns. Our chief view, however, in this is to rescue from oblivion, and affix the gratitude of a nation upon a name dear to us and unknown to those who are exalted, though perhaps unconsciously, by his genius—our parent John Wyatt, of Birmingham.

"To produce something out of nothing is a greater effort of excogitation than to improve what is already produced. The production then of a system of machinery to supersede the artless method of spinning with the fingers, may be justly classed among the highest efforts of mechanical combinations, and this was accomplished early in the last Century by the individual here spoken of. The brief history of the invention, for the narration of which my superior years, and the circumstance of being in possession of his papers and memorandums on the subject, give me an advantage over you, as far as I am able to trace it, is this. In the year 1730, or thereabouts, living then at a village near Lichfield, our respected father first conceived the project and prepared to carry it into effect; and in the year 1733, by a model of about two feet square, in a small building near Sutton Coldfield, without a single witness to the performance, was spun the first thread of cotton ever produced without the intervention of the human fingers, he, the inventor, to use his own words, '*being all the time in a pleasing but trembling suspense.*' The wool had been carded in the common way, and was passed between two cylinders, from whence the bobbins drew it, by means of the twist. This successful experiment induced him to seek for a pecuniary connection equal to the views that the project excited; and one appeared to present itself with Mr. Lewis Paul, which terminated unhappily for the pro-

jector; for Paul, a foreigner, poor and enterprising, made offers and bargains which he never fulfilled, and contrived in the year 1738 to have a Patent taken out in his own name for some additional apparatus, a copy of which I send; and in 1741 or 1742, a mill, turned by two asses walking round an axis, was erected in Birmingham, and ten girls were employed in attending the work. Two hanks of the cotton then and there spun are now in my possession, accompanied with the inventor's own testimony of the performance. Drawings of the machinery were sent to Mr. Cave, for insertion in the *Gentleman's Magazine*.

"This establishment, unsupported by sufficient property, languished a short time and then expired; the supplies were exhausted, but his confidence in the scheme was unimpaired. The machinery was sold in 1743. A work upon a larger scale, on a stream of water, was established at Northampton, under the direction of a Mr. Yeoman, but with the property of Mr. Cave. The work contained 250 spindles, and employed fifty pair of hands. The inventor soon after examined the state of the undertaking, and found great deficiency and neglect in the management. At that time they had spun about 3300 pounds of cotton. On the observations which he then made, he composed what he entitled *A Systematic Essay on the Business of Spinning*, which exhibits a clear view of the mechanical considerations on which an undertaking of that nature, of whatever magnitude, must be established, and apparently confines his humble pretensions to the profit on 300 spindles. It was not within human foresight to calculate the richness of the harvest to come from this little green germ.

"This brings me to the conclusion of our father's connection with the spinning business. The work at Northampton did not prosper; it passed, I believe, into the possession of a Mr. Yeo, a gentleman of the law, in London, about the year 1764; and from a strong coincidence of circumstances there is the highest probability that the machinery got into the hands of a person who, with the assistance of others, knowing how to apply what might be deficient, raised upon it, by a gradual accession of profit, an immense establishment and a princely fortune.

"In the year 1739 my father writes to one of his best friends, '*that by this method,*' some new thought, '*the wool need to be no more carded than to break the knots or mix it well as with scribbles or stock cards, and being thus mixed and pressed down hard into a box, it may, without any human touch, be picked out almost hair by hair and made into yarn.*'

"In 1748 Mr. Paul procured another patent, the title of which was '*for carding of wool and cotton;*' but whether this was combined with the machinery then at Northampton, or where it was introduced, I know not. Such, or nearly such, being the early history of this invention, I thought the late Sir Richard Arkwright would be gratified by possessing the very model to which I have alluded, and I accordingly waited on him at Cromford with the offer, but my reception did not correspond with my expectations.

"To pretend, however, that the original machinery, without addition or improvement, would alone have produced the prodigious effects which we now behold, would be claiming improbable merit for the inventor, and degrading the talents and sagacity of his successors in the same field of enterprise; for it cannot be denied that a great fund of ingenuity must have been expended

Mechanical
Processes.

Manufac-
tures.

in bringing the spinning works to their present degree of perfection. The number of spindles now in use is supposed to exceed 5,000,000.

"If the author of the humble establishment at Birmingham gave birth to such a wonderful progeny, he ought at least to be acknowledged as a benefactor to his Country, and recorded among the men who, from an attachment to the sciences and practice of mechanics, open the path of knowledge and point out, but do not pursue, those which lead to profit and prosperity. Connected with this subject, I might, with great propriety, point out many eminent services that he rendered the public by his mechanical talents; but being mostly local, and absorbed by subsequent productions, they have lost their present interest. The machine, however, for weighing loaded carriages, coal particularly, ought to be distinguished as one of known and extensive utility. It was solely and exclusively his own; he erected the first in Birmingham about fifty years ago, and his own description of it is, *that it would weigh a load of coal or a pound of butter with equal accuracy*. The present makers admit that the principle is incapable of improvement.

"The late Mr. Boulton, a man too eminent and too amiable to be mentioned without esteem and regret, nor on my part without affection, set a high value both on my father's attainments and virtues; for it was universally acknowledged that he had the happiness to give a lustre and an interest to his genius and his knowledge by the purest probity, the most unaffected humility, urbanity, and benevolence. He was attended to his grave, in 1766, by Mr. Boulton, Mr. Baskerville, the celebrated printer, (who, from the peculiarity of his notions, arrayed himself on this occasion in a splendid suit of gold lace,) and four other gentlemen of eminence in Birmingham.

"I am, dear brother, affectionately,
"CHARLES WYATT."

Remarks
on Wyatt's
machines.

(978.) We have thought it right to enter at the length we have done into the claims of Mr. Wyatt; the invention was undoubtedly unsuccessful in his hands, and the machine, in all probability, wanted alterations and improvements which either did not occur to him, or, if they did, were such as his pecuniary means would not allow him to adopt, and it would be as unjust to deny to Arkwright all the merit of rendering perfect what was in its first form defective, as it would be to deny to Mr. Wyatt the honour of the original invention. We have seen that the first Patent is dated 1738; that cotton yarn was spun by means of it in 1741, 1742, and 1743, when the whole seems to have been dropped; it was again revived, or a new Patent taken out, by Paul in 1758, and in 1767 a person of the name of Highe is said to have employed himself in constructing another machine on similar principles; that he employed a clock-maker of the name of Kay to assist him in the brass work; that Kay was afterwards employed by Arkwright, and that the latter thus became acquainted with Highe's invention and availed himself of that knowledge in constructing and completing that machine which was to him, and has been since to many, the source of great riches, and is of such a high and important advantage to the nation at large.

Highe and
Kay's
claims.

We have not the room, neither do there appear to be the materials, necessary for deciding these claims of Highe and Kay; they rest principally upon the testimony of these two persons on a trial, in which Arkwright's Patent was disputed, in 1785. We shall only observe,

that after the Patents of 1738 and 1758, there can be no doubt that by persons interested in such constructions the principles adopted in the Patents would be studied, and important alterations introduced; that such might be the case with Highe; that through Kay, Arkwright might be made acquainted with some additional step taken by Highe, and to these adding certain combinations of his own, as others have still done to his, a machine has been produced which for ingenuity and importance has never been equalled in any Age or nation.

(979.) Arkwright's Patent was enrolled in 1767, under the denomination of the Water Frame, simply from the circumstance of the first machines having been worked by means of a water wheel. We have already referred to the names of two persons, Highe and Kay, and their claims on the invention of Arkwright. There is in fact no doubt, we believe, that Kay was first employed by Highe to make a model of a roller spinning machine, that this Kay was afterwards employed by Arkwright, and that subsequently the latter took out his Patent. Arkwright was not in any way originally connected with the cotton trade, having been born in humble circumstances and apprenticed to a barber at Preston; and only accidentally, as it would appear, fell in with Kay, who was a watch-maker at Warrington, and whom he engaged to assist him in the construction of his first engine, which, there seems every reason to believe, differed very essentially from any other which had hitherto been constructed, but the exact degree of difference it is of course impossible now to decide, although we have a very explicit description of his own machine in the specification of his Patent, with explanatory drawings, which is not the case in Wyatt's original Patent, and as for Highe's machine it is doubtful whether it was ever completed. It would, however, be inconsistent with a concise sketch of this kind, to enter into a minute description of this early form of the roller spinning machine, which is no more like the same machine of the present day than that machine itself was like any of those which had preceded it. We shall reserve, therefore, what we shall have further to add to the subject till we have to describe the modern process of cotton manufacture.

Mechanical
Processes.

Arkwright's
water
frame.

(980.) *Invention of the spinning jenny.*—About two years, or more probably four years, prior to Arkwright's Patent, a machine, altogether of a different description, was invented by a poor man of the name of Hargreaves, and called by him a spinning jenny. Hargreaves was a weaver at Stanhill, near Church, a few miles distant from Blackburn, in Lancashire; he was a plain, industrious, but illiterate man, and possessed little operative mechanical skill. His residence was near the print ground, the first and infant establishment of the late Sir Robert Peel, from whose hints and conversation he derived much important assistance, and whose strong and active mind was at that time engaged in the promotion of every useful improvement connected with that branch of manufacture in which he was afterwards so extensively connected. An anecdote is still recorded in the neighbourhood which ascribes to accident, the parent of so many useful discoveries, the first invention of the jenny. A number of young people were one day assembled at play in Hargreaves' house during the hour generally allotted to dinner, and the wheel at which he, or some one of his family, was spinning was by accident overturned; the thread still remained in the hand of the spinner, and as the arms and periphery of the wheel were prevented by the framing from any contact with

Invention
of the spin-
ning jenny

Manufac-
tures.

the floor, the velocity it had acquired still gave motion to the spindle, which continued to revolve as before; Hargreaves surveyed this with mingled curiosity and attention, he expressed his surprise in exclamations, which are still remembered, and continued again and again to turn round the wheel as it lay on the floor, with an interest which was at that time mistaken for indolence: he had before attempted to spin with two or three spindles affixed to ordinary wheels, holding the several threads between the fingers of his left hand, but the horizontal position of the spindles rendered this attempt ineffectual; it is not therefore improbable that he derived from the circumstance above mentioned the first idea of that machine, which paved the way for subsequent improvement. It consisted at first of only eight spindles turned by bands from a horizontal wheel, in the centre of which was fixed a vertical shaft, with a handle at the top for the spinner. The thread passed between two horizontal pieces of wood the breadth of the machine, which, when pressed together, clasped fast the roving like the finger and thumb of the spinner, and were thus extended or drawn out. He had great difficulty in putting up the thread or winding it on the spindle after twisting, which he at last accomplished by means of a treadle connected with a wire, and worked by the foot of the spinner. The jenny, in its original form, was a rude machine; the first was made almost wholly with a pocket-knife, and the clasp by which the thread was drawn out was the stalk of a briar split in two: it was, as may readily be conceived, defective in the construction of those parts essential to the performance of its work, and which an ordinary mechanic would have had no difficulty in contriving; but Hargreaves was obliged to work in secret, and possessing little mechanical skill, to avail himself of such assistance as he could procure without making public the object he had in view.

Popular prejudice was soon excited against him, and the threats of his neighbours obliged him to conceal his machine for some time after it supplied the woof or weft for his own looms. It was, however, generally known that he had made a spinning machine, and his wife, or some of his family, having imprudently boasted of having spun a pound of cotton during a short absence from the sick bed of a neighbouring friend, the minds of the ignorant and misguided multitude became alarmed, and they shortly after broke into his house, destroyed his machine, and also part of his furniture. Hargreaves soon after removed to Nottingham, whither he was invited by the stocking weavers of that place, and where he assisted in the erection and management of a mill, about the time that Mr. Arkwright first settled there, after being in the same manner driven out, or rather deterred from settling in Lancashire, by the clamour and prejudice of the people. Hargreaves was little qualified, either by education or address, for the sphere of life into which he was removed, and after having assisted various persons in the construction of machinery and communicated to each by turns the whole of what he knew, he died but little enriched by his important discovery. Before he quitted Lancashire he had made one or two wheels of twelve or sixteen spindles, each for some of his relations or friends, and as the popular clamour abated, the number of these increased, till a second mob scoured the whole country and destroyed every machine they could meet with; the value of this improvement, however, was so strongly felt, and the measures adopted against the ringleaders of this outrage were so vigorous

and decisive, that new wheels were immediately constructed, and it was remarked that many of those concerned in opposing their first introduction were amongst the foremost to avail themselves of the advantages they now promised. Various alterations were made in the original machine, which, from its form, was inconvenient and tiresome to grown up persons, though girls of twelve or fourteen managed it with ease. The vertical wheel was substituted for the horizontal one, which rendered it much easier to work; and the treadle, which required an awkward and constrained posture, was rendered unnecessary by a simple contrivance managed by the hand. They were enlarged in their dimensions from twelve to twenty, and afterwards to thirty, fifty, and even eighty spindles, and their use rapidly extended over all the country, though their first introduction every where met with the most determined opposition; even at Nottingham, if our information be correct, a serious affray took place on the first erection of the new machines, in which Hargreaves himself was severely wounded, and a young woman who had accompanied him from Lancashire, and had been accustomed to the management of the first jenny, nearly lost her life.

It has been generally supposed that Hargreaves, at last, died in the parish workhouse, or at least in a state of great poverty; it is satisfactory, however, that we are enabled, on the authority we have frequently quoted, Mr. Baines, to contradict this statement; he gives the following account of the last days of this highly distinguished mechanic. Hargreaves had a partner, Mr. James; and from a son of that gentleman, and from a grandson of Hargreaves, as well as from others, it appears that James Hargreaves went to Nottingham in 1768, and that while in the employment of Mr. Shipley, for whom he made some jennies secretly in his own house, he was induced by the offers of Mr. Thomas James to enter into partnership with him; and that the latter raised sufficient money, on mortgage and loan, to build a small mill at Hockley, where they spun yarn for the hosiers with the jenny. The Patent was obtained in 1770. Finding that several of the Lancashire manufacturers were using the jenny, Hargreaves gave notice of actions against them; the manufacturers met and sent a delegate to Nottingham, who offered Hargreaves £3000 for permission to use the machine; he at first demanded £7000, but at last dropped his demand to £4000, which was, however, resisted. The negotiations being broken off, the actions proceeded, but before they came to trial Hargreaves' attorney, learning that his client, before leaving Lancashire, had sold some jennies, which of course barred his action, gave up the business in despair of obtaining a verdict. The spinning business was carried on by the partners with moderate success, till the death of Mr. Hargreaves, which took place at his own house near the mill in April, 1778. In his will he directed a guinea to be given to the vicar for preaching his funeral sermon, and his widow received £400 from Mr. James for her husband's share of the business, and having other property which her husband had accumulated she left this sum to his children at her death. The reports of his abject poverty are, therefore, erroneous, for although it is certain he did not derive, from his ingenuity, all the pecuniary advantages he so well merited, he, at all events, ended his days in comparatively comfortable circumstances.

(981.) *Invention of the carding machine.*—In order to connect together the two great inventions in cotton spin-

Mechanical
Processes.

Carding.

Manufac-
tures.

Paul's
Patent.

ning we have hitherto said little on a prior process, that of carding; to which the cotton is subjected after it has been opened and cleaned in order that the fibres of the wool may be disentangled, straightened, and laid parallel with each other so as to admit of being spun. It has been already stated that this was formerly effected by hand cards made like flat brushes, but made of short wires instead of bristles, the wires having been stuck through a piece of leather at a certain angle, and the leather then laid on its back on a piece of flat board. These hand cards received some improvements, but the first great step towards the present machine was made by Lewis Paul in 1748. This Patent includes two different machines for the same purpose, the one a plane and the other a cylindrical arrangement of cards. The card is made up of a number of parallel cards with intervening spaces between each, and the material being carded thereon is afterwards taken off each separately, and the several rows or filaments of wool or cotton so taken off are connected into one entire roll.

The first machine consisted of a flat board varying in dimensions from three feet by two feet to two feet by fourteen inches, on which were nailed sixteen long cards parallel to each other, with small spaces between each two; but the second, which may be considered as the model of the present carding engine, was a horizontal cylinder, covered in its whole circumference with intervening spaces. Under the cylinder was a concave frame lined internally with cards exactly fitting the lower half of the cylinder, so that when the cylinder was turned, the cards of the concave frame worked against those on the cylinder and carded the cotton or other material passed between them. When the wool was sufficiently carded it was stripped off by means of a stick with needles in it parallel to one another like the teeth of a comb. The cardings were of course only the length of the cylinder, but an ingenious apparatus was attached for making them into a perpetual carding. Each piece was placed on a flat broad riband which was extended between two short cylinders, and which wound upon one cylinder as it unwound from the other. When the carding was placed on the riband, the turning of one of the cylinders wound the riband and carding upon it, and being joined length to length the carding or sliver was made perpetual, and was wound up in a roll ready for the spinning machine.

This apparatus, which is undoubtedly in its principle of operation the same as the modern carding engine, was turned only by hand, and was in other respects defective, yet it displayed the talents of its inventor to advantage, although it does not appear that he benefited much by it in a pecuniary point of view. Its defects were that the cylinder had no feeder, the wool having to be put on by hand; that the cardings were taken off separately by a movable comb, which required the machine to be stopped; and the perpetual carding was produced only by joining together short lengths by hand; lastly it was turned by hand, and of course with great labour. We shall see, as we proceed, how admirably all these objects are accomplished in combination with the spinning process almost without manual labour or mental attention.

(1782.) *Invention of the mule.*—There still remained an important step to be made in the art of cotton spinning, for which the nation is indebted to Mr. Samuel Crompton. This is called the mule, or mule jenny, from its combining the principles of the roller spinning of

Arkwright with the spinning jenny of Hargreaves; like the former it has a system of rollers, and like the latter it has spindles without bobbins to give the twist, and the thread is stretched and spun at the same time by the spindles after the rollers have ceased to give out the rove. The great difference between this and the two former machines is, that instead of the spindles being stationary they are placed on a movable carriage, which is wheeled out to distances of from four to five feet from the roller beam, in order to stretch and twist the thread, and then wheeled in again to wind it up on the spindles. This important improvement, as we have stated, was made by Samuel Crompton, a weaver of respectable character and moderate circumstances, living at Hall-in-the-Wood, near Bolton, about the year 1775, or rather perhaps between the years 1774 and 1779, for it does not appear that he had rendered it perfect before the latter year, although he had conceived the idea of it, and commenced working upon it in 1774. Crompton was of a retiring and unambitious disposition, he therefore sought no aid and took out no Patent, and only regretted that public curiosity would not allow him to enjoy his invention as his own, and to earn by his manual labour undisturbed the fruits of his ingenuity and perseverance; from which indeed he might have reaped considerable advantages, as the great perfection of his yarn ensured to him plenty of customers and high prices. Cotton yarn is designated by different numbers, as No. 40, No. 60, No. 80, &c., implying that there are so many hanks to the pound, the length of each hank being always 840 yards. For No. 40 he obtained fourteen shillings per pound; for No. 60, twenty-five shillings; and for No. 80, forty-two shillings, the latter No. having been thought (till he produced it so fine) an actual impossibility; but such has since been the extent of improvement that No. 100 is now sold for three shillings per pound, and while a few years back No. 80 was considered as a wonder, there has been produced No. 350, that is, three hundred and fifty hanks, each eight hundred and forty yards long, have been spun, weighing only one pound.

As in the cases of the roller spinning engine and the spinning jenny, the mule was in its first form very imperfect compared with what it is at present: it at first consisted of not more than twenty or thirty spindles; in a subsequent stage the number of spindles were increased to 100 and 130, then came the double mule with a greater number, and at the present day there are mules working in Manchester and other places in which the number of spindles vary from 800 to 1100, and the double mules to the prodigious number of 2200. Notwithstanding the extraordinary importance of this invention, the machine not being secured by a Patent, the inventor rose but little out of the sphere of life he was in originally, till in 1812 the value of the apparatus was represented to Parliament, by whom was granted to him a reward of £5000; with this sum it appears he set his sons up in the cotton printing trade, but through misfortune and mismanagement it was all sunk, and the inventor at length was left to subsist upon a pension or annuity raised for him by private subscription, amounting to £63 per annum, and for which he was much indebted to the kind consideration and active benevolence of Mr. Kennedy, who afterwards published a brief memoir of him.

We must here conclude our historical sketch of the improvements in cotton spinning, not for want of materials, but for want of space; for every year during the

Mechanical
Processes.

Invention
of mule
spinning.

Manufac-
tures.

present century has been adding improvements upon improvements: we must therefore be content with simply mentioning the names of a few of the many contributors towards the perfection to which this operation is now arrived; of these we may enumerate Messrs. Eaton, of Wilne in Derbyshire; Mr. Dyer and Mr. Peter Ewart, of Manchester; Mr. De Jongh, of Warrington; Mr. Buchanan, of Catrine Works; Mr. Knowles and Mr. Roberts, of Manchester; Mr. Kelly, of Lanark; to whom we might add many others having like claims to honourable distinction.

Summary
of the
several
inventions.

We have already repeatedly acknowledged our obligations for many of the facts contained in the preceding sketch to the *History of the Cotton Manufacture*, by Edward Baines, jun. Esq.; we are also under obligation to Mr. Guest, and for some facts to the *Encyclopædia Britannica*; we beg also to add one other abstract from the Author first named, with which he concludes his interesting history of cotton spinning.

"Having thus," he observes, "traced the spinning machinery up to the present time, let us pause to cast a retrospective glance on the different stages by which the process of spinning has advanced from the time when the one-thread wheel was in general use. Little more than sixty years since every thread used in the manufacture of cotton, wool, worsted, and flax throughout the world was spun singly by the fingers of the spinner with the aid of that *classical* instrument, the domestic spinning wheel. In 1764 an *eight-handed* spinster sprung from the genius of Hargreaves, and the *jenny*, with still increasing powers, made its way into common use in spite of all opposition. Two years afterwards the more wonderful invention of Wyatt, which claims a much earlier origin, but which had disappeared like a river that sinks into a subterraneous channel and now rose again under the fortunate star of Arkwright, claimed yet higher admiration, as founded on principles of more extensive application. Five years later, the happy thought of combining the principles of those two inventions to produce a third much more efficient than either, struck the mind of Crompton, who, by a perfectly original contrivance, effected the union. From twenty spindles this machine was brought, by more finished mechanism, to admit of a hundred spindles, and thus to exercise a *Briarean* power. Kelly relinquished the toilsome method of turning the machine by hand, and yoked to it the strength of the rapid Clyde. Watt, with the subtler and more potent agency of steam, moved an iron arm that never slackened or tired, which whirls round two thousand spindles in a single machine. Finally, to consummate the wonder, Roberts dismissed the spinner and leaves the machine to its own infallible guidance. So that in the year 1834 several thousand spindles may be seen in a single room revolving with inconceivable rapidity, with no hand to urge their progress or to guide their operations; drawing out, twisting, and winding up as many thousand threads with unfailing precision, indefatigable patience and strength; a scene as magical to the eye which is not familiarized with it, as the effects have been marvellous in augmenting the wealth and population.

"If the thought should cross any mind that, after all, the so much vaunted genius of our mechanics has been expended in the insignificant object of enabling men better to pick out, arrange, and twist together the fibres of a vegetable wool; that it is for the performance of this minute operation that so many energies have been

exhausted, so much capital employed, such stupendous structures raised, and so vast a population trained up; we reply, our object is not insignificant because the operation by which it is effected is *minute*; the first want of men in this life, after food, is *clothing*, and as *this* art enables them to supply it far more easily and cheaply than the old methods of manufacturing, and to bring cloths of great elegance and durability within the use of the humble classes, it is an art whose utility is inferior only to that of agriculture. It contributes directly and most materially to the comforts of life among all nations where manufactures exist, or to which the products of manufacturing industry are conveyed; it administers to the comfort and decency of the poor, as well as to the taste and luxury of the rich. By supplying one of the great wants of life with a much less expenditure of labour than was formerly needed, it sets at liberty a larger proportion of the population to cultivate literature, science, and the fine arts. To this country the new inventions have brought a material accession of wealth and power. When it is also remembered that the inventions, whose origin I have endeavoured carefully to trace, are not confined in their application to one manufacture, however extensive, but that they have given nearly the same facilities to the woollen, the worsted, the linen, the stocking, and the lace manufactures as to the cotton; and that they have spread from England to the whole of Europe, to America, and to parts of Africa and Asia; it must be admitted that the mechanical improvements in the art of spinning have an importance which it is difficult to over estimate. By the Greeks, their authors would have been thought worthy of deification; nor will the enlightened judgment of moderns deny that the men to whom we owe such inventions deserve to rank among the chief benefactors of mankind.

"The dissolution of Arkwright's Patent, and the invention of the mule, concurred to give the most extraordinary impetus to the cotton manufacture. Nothing like it has been known in any other great branch of industry. Capital and labour rushed to this manufacture in a torrent, attracted by the unequalled profits which it yielded. Numerous mills were erected and filled with water frames, and jennies and mules were made and set to work with almost incredible rapidity. The increase of weavers kept pace with the increase of spinners; and all classes of workmen in this trade received extravagantly high wages; such as were necessary to draw from other trades the amount of labour for which the cotton trade offered profitable employment, but such as it was impossible to maintain for any lengthened period."

(983.) In concluding our sketch of this division of the cotton manufactures of Great Britain, it will be interesting to the reader to see the increase of importation of cotton-wool, and in the export of cotton twist, during the latter and the present century.

Cotton
weaving.

(984.) *Cotton weaving.*—We propose to treat of the Art of weaving in a separate article, after having described the methods employed for reducing various materials, as flax, wool, silk, &c., to a form proper for the weaver; and in order to complete our sketch of the history of the cotton manufacture generally, it is necessary slightly to refer to the process of weaving, which we accordingly have done in the following columns; but for a more particular description of weaving generally, the reader must consult the article above mentioned.

The old hand loom, which is still employed in many places where the worsted manufacture is carried on, is too well known to require a minute description. It consists of a large wooden frame with a roller or beam at one end on which the warp is wound, and another at the other end where the weaver sits, to wind up the piece as it is woven. The weaver sitting with his feet upon what are termed treadles, opens thereby with his treading the threads of the warp, and reaching at his full stretch, his breast bearing against a fixed beam, he throws the shuttle backwards and forwards with his hands, but alternately removing one of them to drive the weft or shoot up close with a swinging part called the boards or lathe. When the stuff was of so great a breadth that one man could not reach, then two men became necessary.

Such was also the form of the cotton loom till about the year 1738, when a great improvement was made by

John Kay. This consisted in lengthening the lathe sufficiently at each end to receive the shuttle in a box, instead of the weaver receiving it into his hand; and by means of two strings fixed to a movable piece in each box, the strings being united to a short peg in the centre, the workman by a smart jerk struck the shuttle from side to side with his right hand, while his left was steadily applied to the lathe. His position thus became upright and easy compared with the former constrained and leaning posture. By this invention considerably more work could be done, the thickness of the cloth was preserved more uniform, and the health of the weaver greatly improved.

Another improvement was afterwards made by the same person in what is called the drop box. This comes into application in those goods requiring two or more shuttles where the weft is of different colours, which required formerly the weaver to stop and change his shuttles after a certain number of throws, whereby much time was lost; but by Kay's contrivance the box contained the two shuttles, and by suddenly raising or depressing it any shuttle might be thrown, and in any order of succession, without any let or delay. This form of loom, with certain minor improvements in the lightness of the construction and neatness in the working parts, is that which is still employed by the hand-loom weavers, and will require no further description. We proceed, therefore, at once to an account or history of the invention of the power loom.

(985) *Power loom.*—It is remarkable that, the power loom being of such recent introduction, our first notice of it is so early as the year 1678, when a Paper was read to the Royal Society, and afterwards printed in the *Philosophical Transactions*, under the title of *A New Engine to make Linen Cloth without the help of an Artificer*, by M. de Gennes. This description, with an illustrative plate, is preserved by Dr. Hutton in his *Abridgement of the Transactions*, vol. ii. p. 439. It is needless, however, to enter into particulars of it in this place, as it was probably never more than a creature of the imagination, and was never attempted to be carried into real practice. It differs greatly, as may be supposed, from the present power looms, but the idea was the same, and in other times it is probable the ingenious inventor might have made it effect his intended purpose, which is stated to be, first, "that one mill alone will set ten or twelve looms to work; secondly, the cloth may be made of

Hand loom
and fly
shuttle.Power loom
projected in
1678.

Manufac-
tures.

what breadth you please, or at least much broader than any which has been hitherto made; thirdly, there will be fewer knots in the cloth, since the threads will not break so fast as in other looms, because the shuttle that breaks the greater part can never touch them. In short, the work will be carried on quicker and at less expense, since, instead of several workmen which are required in making of very large cloths, one boy will serve to tie the threads of several looms as fast as they break, and to order the quills in the shuttle."

Cart-
wright's
power loom.

(986.) An attempt, carried to a much more practical extent, was again made in 1765, by what was called the swivel loom, which was however soon abandoned; but in 1784 a close approximation to the present power loom was proposed by Dr. Cartwright, who has given the following account of the motives which first led him to the undertaking.

"Happening to be at Matlock in the Summer of 1784, I fell in company with some gentlemen of Manchester, when the conversation turned on Arkwright's spinning machinery. One of the company observed, that as soon as Arkwright's Patent expired so many mills would be erected, and so much cotton spun, that hands never could be found to weave it; to this observation I replied, that Arkwright must then set his wits to work to invent a weaving mill. This brought on a conversation on the subject, in which the Manchester gentlemen unanimously agreed that the thing was impracticable; and, in defence of their opinion, they adduced arguments which I certainly was incompetent to answer, or even to comprehend, being totally ignorant of the subject, having never at that time seen a person weave. I controverted, however, the impracticability of the thing by remarking, that there had lately been exhibited in London an automaton figure which played at chess. Now you will not assert, gentlemen, said I, that it is more difficult to construct a machine that shall weave than one which shall make all the variety of moves that are required in that complicated game.

"Some little time afterwards a particular circumstance recalled this conversation to my mind. It struck me that as in plain weaving, according to the conception I then had of the business, there could only be three movements which were to follow each other in succession, there would be little difficulty in producing and repeating them. Full of these ideas, I immediately employed a carpenter and smith to carry them into effect. As soon as the machine was finished, I got a weaver to put in the warp, which was of such materials as sail cloth is usually made of. To my great delight a piece of cloth, such as it was, was the produce. As I had never before turned my thoughts to any thing mechanical, either in theory or practice, nor had ever seen a loom at work, or knew any thing of its construction, you will readily suppose that my first loom was a most rude piece of machinery. The warp was placed perpendicularly, the reed fell with the weight of at least half a hundred weight, and the springs which threw the shuttles were strong enough to have thrown a Congreve rocket. In short, it required the strength of two powerful men to work the machine at a slow rate and only for a short time. Conceiving, in my great simplicity, that I had accomplished all that was required, I then secured what I thought a most valuable property by a Patent, 4th of April, 1785. This being done, I then condescended to see how other people wove, and you will guess my astonishment when I compared their easy modes of

operating with mine. Availing myself, however, of what I then saw, I made a loom, in its general principles nearly as they are now made. But it was not till the year 1787 that I completed my invention, when I took out my last weaving Patent August 1st of that year."

Subsequently, the inventor established a weaving mill at Doncaster, but it did not succeed; he obtained, however, from Parliament a grant of £10,000 as a reward for his ingenuity.

Another undertaking of the same kind by Messrs. Grimshaw, executed under Dr. Cartwright's Patent, failed, after trial at Knott Mills, Manchester, in 1790. Another was again made and abandoned in 1794 by Mr. Bell of Glasgow. In 1796, another Patent was taken out by Mr. R. Millar of Glasgow, which was adopted by Mr. John Monteith in 1801, and after indifferent and variable success was at length made to answer the intended purpose.

It appears that the greatest impediment to the more early success of the power loom was the necessity of dressing the warp as it unrolled from the beam. In the old hand loom this operation, which is intended to lay down smoothly the floss or feathers of the cotton twist previously to their passing through the reed, was effected by two long brushes which were dipped or covered with size or starch, the one being applied under and the other over the unwound warp which was brushed or dressed by the weaver, and when this part was nearly woven up another dressing was given, about yard by yard or a little more.

(987.) This operation was a great inconvenience in power-loom weaving, but it was at length fortunately avoided by giving to the warp a sufficient dressing in the first instance by a new invented dressing machine; and from that time every difficulty has been gradually vanishing, so that there is little doubt that the old hand loom will be ultimately wholly superseded. The dressing machine is due to a weaver of the name of Johnson, one of the workmen of Messrs. Radcliffe and Ross, of Bradford, at whose charge the expense of the experiments and Patent were sustained. The yarn is first wound from the cop upon bobbins by a winding machine, in which operation it is passed through water to increase its tenacity. The bobbins are then put upon the warping mill, and the web warped from them upon a beam belonging to the dressing frame. From this beam, placed now in the dressing frame, the warp is wound upon the weaving beam, but in its progress to it passes through a hot dressing of size. It is then compressed between two rollers to free it from the moisture it had imbibed with the dressing, and drawn over a succession of tin cylinders heated by steam to dry it; during the whole of this last part of its progress being lightly brushed as it moves along and fanned by rapidly revolving fanners. The dressing here spoken of is merely a size or paste made of flour and water, now generally used cold, and the use of it is to make the minute fibres which, as it were, feather the yarn, adhere closely to it so that the warp may be smooth like catgut. The brushes essentially aid in smoothing the yarn and distributing the size equally over it, and by means of the fan and the heated cylinders the warp is so soon dried, that it is wound upon the beam for the loom within a very short space after passing through the trough of paste. This machine, from the regularity and neatness of its motion and its perfect efficacy, is equally beautiful and valuable.

Manufac-
tures.

This mode of dressing rendered the power loom available, (although the process is now superseded by a simpler one in some establishments,) and successive improvements have at length, perhaps, brought it to its greatest attainable perfection. The first new Patent for a power loom, after the invention of the dressing frame, was taken out by Mr. H. Horrocks in 1803, further improvements in which were patented in 1805, and again in 1813. Another Patent by Mr. P. Marsland was enrolled in 1806; this had a double crank and made superior cloth, but was much more complex than the former, which is the one now principally adopted.

Estimated
number of
the power
and hand
looms in
England
and Scot-
land.

The number of power looms in England and Scotland has been increasing from the date of the last Patent, in 1813, in a surprising degree, as will appear by the following statement given by Mr. Baines, from whose Work the following abstract has been formed.

Number of Power Looms in England and Scotland in the Years 1820, 1829, and 1833.

1820, Number of power looms in England	12,150
Ditto Scotland	2,000
1829, Number of power looms in England	45,500
Ditto Scotland	10,000
1833, Number of power looms in England	85,000
Ditto Scotland	15,000

With this wonderful increase in the number of power looms, it is extraordinary that the number of hand looms are not diminished, but seems rather to have increased. The number of the latter in 1820 was estimated by Mr. Kennedy at 240,000, and in 1833 they were stated by Mr. Grimshaw at 250,000. See *Parliamentary Report on Manufactures*, p. 608. This exceeds, however, the estimate made by Mr. George Smith, at p. 566 of the *Report*, who considers them as only amounting to 200,000, but Mr. Baines inclines to the former estimate as the most probable. The number of hand looms in Scotland, in 1834, appears to have been about 45,000 or 50,000.

With respect to the work that can be performed with these power looms as compared with the work that can be done by the hand loom, and the increasing quantity which every successive improvement enables the power loom to perform, the following was given by a manufacturer to Mr. Baines as a correct statement.

"A very good *hand weaver*, twenty-five or thirty years of age, will weave *two* pieces of $\frac{2}{8}$ shirtings per week, each twenty-four yards long, containing 100 shoots of weft in an inch, the reed of the cloth being a forty-four Bolton count, and the warp and weft forty hanks to the pound.

"In 1823 a *steam loom weaver* about fifteen years of age, attending two looms, could WEAVE seven similar pieces in a week.

"In 1826 a *steam loom weaver* about fifteen years of age, attending two looms, could weave twelve similar pieces in a week; some could weave fifteen pieces.

"In 1833 a *steam loom weaver* from fifteen to twenty years of age, assisted by a girl about twelve years of age, attending to four looms, can weave *eighteen* similar pieces in a week; some can weave twenty pieces."

We shall here conclude our sketch of the history and extraordinary progress of the cotton manufactures of Great Britain, and shall now endeavour to describe concisely, but with a little more detail than could be introduced into the preceding pages, the successive steps of this manufacture as they are pursued in the most improved modern establishments.

Description of the Processes employed in the Cotton Manufacture.

(988.) In the preceding historical sketch we have spoken only of those branches of the cotton manufacture in which great and important inventions have been employed to perfect and expedite several of the mechanical processes, but we have not entered into minutiae, nor have we attempted to describe the several steps *seriatim* as they are now practised in our larger mills; this will be the subject of the following articles.

The pods of cotton are opened in the Country in which it grows, whether Egypt, America, or India; the wool is then packed into large bags, in which it is received at the cotton mill in Manchester or elsewhere. It has then to undergo the following processes; *viz.*, it has to be batted, carded, and formed into slivers, doubled, drawn, roved, spun, and wove, requiring intermediate operations which will be described as we proceed.

Mechanical
Processes.

Processes
described.

Manufactures.
Cleaning and batting.

(989.) *Cleaning and batting.*—The first operation the cotton has to undergo, after being unpacked, is to clean it from all the seeds or motes it may contain previously to its being carded. This was formerly performed wholly by hand, and is still so in some manufactories and for certain goods. A long frame, about the height of a common table, is formed, with sides and a bottom, of parallel cords laid pretty closely, and upon this the cotton wool is laid, opened a little by the hand and then beaten by the batter, who uses a light willow stick in each hand, and as he raises the sticks he opens and shakes the cotton, thereby clearing it of the seeds and other dirt, which fall through the corded bottom of the batting frame. But this operation, except for the finer cotton, is now effected by machines; there are several kinds, of which the following is perhaps the best.

Batting and scutching machine.
Pl. lxix.
Fig. 1

This machine, represented in plate lxix. fig. 1, resembles in some measure the thrashing machine. The cotton is fed through rollers, and struck by scutchers moving at a great velocity, which operation opens the cotton, at the same time it is blown by fanners, which serve further to open it, and to separate the lighter and finer parts, while the gin or seeds, sand, &c. are driven or fall through a grating made of wire.

The cotton, as taken from the bag, is spread on the feeding cloth A B, which conveys it forward to the feeding rollers. C E are two of the scutchers which, moving at a great velocity in the direction expressed by the arrow, strike and open the cotton as it is fed in by the rollers, while a strong current of air, produced by the motion of the fanners G H I, acts upon it. The gins, sand, &c. are driven through the circular grating L M, and fall on the angular grating N O. Q R is a long grating which is level, and through which any remaining lumps or gins pass, while the cotton is blown forward to a small apartment or closet from which it is from time to time removed. For fine spinning it is then ready to be picked by hand to take out any remaining motes, but for ordinary spinning it is taken immediately from the batting machine to the carding engine.

This improved batting machine not only saves much labour and expense, but, from the manner in which the cotton is enclosed during the operation, much dust, film, &c. is prevented from escaping, which, as the process was formerly conducted, was most prejudicial to health.

The scutcher is 14 inches in diameter, and makes from 1200 to 1400 revolutions per minute. The feeding rollers, one and three-fourth inches in diameter, go one revolution for sixty of the scutchers. The fanners, twenty-two inches in diameter, have the same speed as the scutchers. The circular grating under the scutchers is one inch in diameter in the wires, all the others have their wires about three-eighths of an inch distant from each other.

Carding and carding machine.
Fig. 2, 3, 8, 9.

(990.) *Carding.*—The next operation is that of carding, by means of which the cotton, opened and cleansed at the batting or scutching machine, is carded or combed, the fibres spread and laid evenly and parallel to each other. To the several improvements in this process we have had occasion to refer in our historical sketch. We have seen that this operation was first performed by hand cards, then by double cards, stock cards, and then by machinery with plane cards, then by cylinders; but in all cases the carding was removed by hand, in cardings the length of the card or cylinder, then the same was produced by an apparatus attached to the machine, till at length Arkwright took out his Patent for continuous

carding which produces the sliver in one long length. A representation of this machine in its most improved form is given in plan and elevation in fig. 2, 3, where A is the large cylinder covered with cards, (see description, p. 310,) the sheets of leather for which are glued or nailed on in strips or sheets parallel to its axis, and disposed in such a manner that when the cylinder revolved in the direction of the arrow the teeth upon it, see fig. 8, 9, go with their points forward, so that if a piece or knot of cotton were held against them it would be drawn inwards upon the teeth. This cylinder is driven by a band passing over the pulley or drum R, being connected with the first mover, whether it be a water-wheel or steam-engine. This cylinder revolves under an arch C C, fig. 3, lined with the same kind of cards, the teeth being so disposed as to meet those of the cylinder; this is supported on two iron arches fixed on each side of the cylinder, these having spokes on them on which the several pieces that form the arch are fastened.

B is a second cylinder of cards, these being laid in spirals, revolving much slower than the former, its motion being communicated by wheelwork driven by a wheel on the axle of the larger cylinder A; D is the feeding cloth on which the cotton received from the scutching machine is spread; this traverses constantly round two rollers which are likewise turned by a communication with the wheel on the axle of the principal cylinder. The cotton being spread on the feeding cloth as above described, and the machinery put in motion, it advances slowly with the cloth and is thus thrown in between the two feeding rollers which deliver it gradually and equably to the carding cylinder, which carries it round and works it against the fixed cards under the arch C. In this process it becomes very equably distributed over the teeth of the cylinder. The cotton continues thus hanging sometimes in the teeth of the cylinder and sometimes in those of the arch, but advancing slowly from one tooth to the next till it has passed clear through the arch, when it comes to the small cylinder B, which, as already stated, is revolving slowly in such a direction that its surface moves the same way as the cylinder but much slower, and its teeth meeting those of the cylinder. The teeth of this small cylinder having no cotton upon them receives about half what is upon the teeth of the cylinder A, and as it constantly turns round and brings up fresh empty teeth, these in their turn take away the cotton, so that it is continually carried from this in a uniform stream, which is as uniformly supplied by the feeding cloth and rollers. The cotton thus received upon the cylinder B proceeds downwards with it, but as it again ascends, a *taker off*, which is a sort of steel comb, keeps continually stripping off the fleece by an alternate and rapid motion, so as to remove it from this cylinder in a continuous fleece; this fleece is sometimes again spread on the feeding cloth of a similar machine, and is in the second process carried, in the form shown in the figure, through two rollers to compress it, and is then delivered into a tin can or cylinder S placed to receive it.

(991.) *The drawing frame.*—The next process is that of doubling and drawing, the machine for which is represented in fig. 4, 5. The object of this is to combine and recombine several slivers into one, and at the same time to draw and lengthen them, to equalize the thread, and to render it of more uniform strength and texture.

The drawing frame, fig. 4, is of itself so explanatory of the process as scarcely to require any description:

Mechanical Processes.

Drawing frame.
Fig. 4, 5.

Manufac-
tures.

A, B, C, &c. are cans brought from the carding engine; the sliver in each is passed through two or three pair of drawing rollers *ee, ff*, &c. the latter moving with four or six times the velocity of the first pair; this reduces each sliver proportionally less than its original size, but the whole being ultimately united by passing through the funnel *g* seen in the figure, they fall in one combined sliver into a can as before, the fibres by this process having been further straightened, and any inequality in the first sliver thus reduced. This operation is performed several times, but greater or fewer, according to the quality of the goods intended to be manufactured; on some occasions it is repeated, till each sliver contains portions of several thousands.

Roving
apparatus,
or roving
billy.

(992.) *Roving machine*.—This, like most of the other machinery, has passed through many forms, and has received different denominations; the object of the operation is to reduce the sliver as obtained by the doubling and drawing machine into a finer sliver or roving, and to give it such a twist as shall reduce it to the form of a large coarse line or yarn. In this process the sliver is made to pass through pairs of rollers, which, differing from each other in speed, draws them out finer and to a greater length, and ultimately to give to the roving the twist requisite to fit it for the process of spinning. The first idea was to receive it into cans, which were themselves revolving by a detached portion of the engine power, and by means of which the thread was twisted as it fell into the can, and the operation was accordingly denominated can roving, and it is still practised in some manufactories. Another process has been denominated the jack-frame roving, and another the spindle and flier roving; which latter being now commonly adopted is that we propose to describe. The roving frame is of considerable length, carrying on one side a number of spindles, on which are placed bobbins to receive the rovings after they have acquired the twist which is the object of this operation; the cans from the doubling and drawing machine are arranged on the other side, and the sliver of each is brought from the can, passed through rollers, and thence through a flier on the top of each bobbin, as represented in fig. 6: one branch of this flier is tubular, marked *g*, and through this the sliver is brought to the bobbin. The machine being now put in motion, the twist is given to the sliver by the revolving of the flier as it enters at *r*, and is drawn forward at the same time through the tubular part *g*, by winding on the bobbin *p*, the bobbin and flier revolving with different velocities, the former being loose on the spindle which carries the flier. The bobbin is made to revolve by a band passing over the pulleys *ii* on which it rests, and the spindle and flier by a band passing over the pulleys *hh*. It will be observed that, as the roving is always winding from the lower end of the flier *g*, it is necessary that the bobbins should be made to ascend and descend as they revolve, so that the roving may be laid evenly and smoothly upon them. This rising and falling motion is produced in different ways. According to the plan indicated by the drawing, it is effected by the gradual ascent and descent of the bar *NN* on which the pulleys rest, and which is shown in the figure referred to; by this contrivance the roving falls close to but not upon the former turn, thus disposing it regularly through all the length of the bobbins, and when the latter have descended to the lowest point, they gradually rise again, then fall, and so on, till they are filled and removed

by the boy or girl attending to the machine, whose business is then to supply other bobbins, and to unite any of the rovings that may separate as the operation proceeds. The can roving differs from the above only in this, that instead of the roving being wound on bobbins it was allowed to fall into a can and to receive its twist by the revolution of the can. The latter process was that first adopted by Arkwright, but for which he afterwards substituted the spindle and fly, in which the great difficulty to be overcome was that the bobbins, when they became filled with rovings, being much heavier than when empty, required much more force to drag them round. The bobbin at first was made to rest on the rail *N*, and was retarded from moving so fast as the spindle by friction only. Had it moved equally fast with the spindle, it is obvious it could not have taken up the roving, and had it been stationary, the flier would have had the effect of stretching and breaking the roving. The bobbin, therefore, required to have a motion, but a slower one than the spindle, and that motion also required to become slower as the bobbin filled, in consequence of the greater circumference. All these difficulties are, however, avoided in the present roving machine, by means of the double motion or speed given to the bobbin and spindle as above described. We have already stated, that at every revolution of the bobbin the rail *N* gradually rises, and then gradually falls; besides which, it will be seen from what has now been stated, that it is necessary after each ascent and descent that the speed of the bobbins should be made proportionally slower, that the quantity wound up in a given time or in a given number of revolutions may be the same, and consequently the stretching force on the roving the same also.

The mechanism, by means of which this change in the velocity of the bobbin is accomplished, is different in different mills or in different machines. We may shortly describe the two methods most approved. In some machines it is produced by means of two conical barrels of the same dimensions, but placed with the larger end of the one opposite the smaller end of the other. The one of these barrels, moving uniformly, communicates motion to the other by an endless strap, which, by being shifted towards either extremity, varies the motion of the other barrel. The belt or strap remains equally tight in every part, for the one barrel increases in diameter exactly as much as the other decreases. From the second barrel motion is conveyed to the pulleys resting on the bearer *NN*, and having the spindles passing through the centre of each; the bobbins rest on those pulleys, and are carried round with them.

In other machines, instead of the conical barrels, two wheels having no teeth but covered with leather, the one bearing on the face of the other, moves it by contact, and varies the motion by approaching and receding from the centre of the face wheel. For a more particular account of these two pieces of mechanism, and other similar contrivances, see article (77.) of the present Treatise.

(993.) *Jenny spinning*.—The cotton being prepared by the preceding processes is now in a state for spinning either by the roller, or as it is commonly called water-spinning, or by the mule; but for jenny spinning, the doubling and drawing process is not essential. We have already referred to this mode of spinning in our historical sketch, and to the trifling accident which gave

Mechanical
Processes.

Manufac-
tures.

rise to it; it in fact very much resembles the hand spinning, but is so contrived that one person works a number of spindles at the same time; it resembles also in some measure the roving billy, but differs from it in construction in this respect, that the clasp is attached to the carriage while the spindles are disposed on the rails of the frames which remain at rest. The drawing out of the clasp stretches the rove so as to reduce it to the size proper for the yarn, at the same time the spindles twine it. During the return of the carriage, the yarn is built on the spindles by levers and wires and formed like the rovings in the roving billy into cops, which are afterwards drawn off the spindle, as with the common spindle and distaff. It is wrought by hand by one person, who is assisted by a boy or girl called a *piecer*, whose business is to mend such threads as break. The yarn when taken off the spindle is sometimes reeled, but more frequently given to the weaver in cops, who has it wound on the bobbins or *pirns* preparatory to its being placed in the shuttle. Common jenny spinning is now but little used except for the web of calicoes; for this purpose it is preferred to that produced by the mule, as it gives the cloth a more rich and full appearance.

Roller spin-
ning.
Fig. 7.

(994.) *Roller and fly or water spinning*.—This we have already described in a general way, in speaking of Arkwright's invention; it remains now to describe it a little more in detail, leaving out of consideration the disputed claims to the actual discovery. Of the nature of the operation a general idea may be formed from the preceding description of the roving machine with spindle and flier; but as the thread in spinning has sufficient strength to bear the drag of the bobbin, no mechanism for regulating the speed of the latter is in this case necessary, so that the bobbin resting on the rail or bearer is retarded by friction only. We have represented one single thread undergoing the operation of spinning, in plate lxix. fig. 7, availing ourselves in this case of the description given of it by Mr. Duncan, in the *Edinburgh Encyclopædia*. A is the binder or pulley loose on the axle C D. This binder is kept in motion by a broad belt from a drum on an upright shaft of the millwork; E is the fast pulley fixed on the axle C D. In order to disengage and re-engage the axle C D from the fast pulley E, and thereby to stop or set going the head of spinning connected with it, the locking bayonet is used. This, which is described at article (51.) consists of a kind of fork *abcd*, which passes through two holes in the fast pulley E. The bayonet is movable upwards and downwards on the axle C D, which passes through its collar *c b*. Round this collar there is a groove, into which part of what is called the *lifter* projects, and by means of which the bayonet is by hand at pleasure raised or depressed. While the bayonet is in the situation represented in the figure, the binder A keeps running on its bush, and the axle C D is at rest.

In order to set the axle in motion, the bayonet is depressed, and its leg *a* and *d* lay hold of two projecting teeth or pieces of iron, in a groove in the upper end of the binder A. The fast pulley E is thus locked or connected with the binder, whereby the axle and pulley are carried round together, and thus motion is given to the whole of the moving part of the thread. This contrivance is also used for disengaging the drums on the upright shafts of the millwork, and was also used in Arkwright's can roving frames, and various other parts of cotton machinery; but the fast and loose pulley

already described has now in many instances superseded the bayonet, to which it is to be preferred in all situations where circumstances will allow of its application, as by it the belt carries the pulley into motion without any shock. A great improvement on the locking bayonet has, however, of late years been introduced. Instead of making it, when thrown into gear, strike against permanently fixed teeth, or a fixed *clutch*, it strikes against the ears of an iron hoop which embraces a fixed pulley, and thus prevents the machine being so suddenly jerked into motion when the bayonet is let down. See the article *MILLWORK*, p. 101. The elementary process of drawing (or further reducing the roving into a size proper for a fine thread) is performed in the spinning frame by fluted rollers similar to those of the roving frame, to which motion is given in the following manner. On the top of the axle C D is a pinion F which works into a face wheel, represented by a dotted circle, (in order that the rollers may be better seen, of which a vertical section is shown in the figure,) fixed on the end of the front roller *e*, from which, by a train of wheelwork, motion is communicated to the middle roller *f* and the back roller *g*. This train of wheelwork is calculated so as to produce the requisite drawing effect. Between the middle and back rollers there should be a little more draw than is necessary to pull the rove from the back rollers, for it is found that the thread is more even when the fibres are pulled by the front rollers. The back rollers serve to keep the roving from being pulled too fast forward; the top roller *h*, in the middle, is much lighter than the other top rollers, and permits the fibres to move freely among themselves in reducing the roving. G H represents the spindle, to which motion is communicated from the fast pulley E, by means of a strap formed of cloth listing I K, which goes round the spindle shaft at I; *i k l* is the flier, the legs of which consist of two solid pieces of iron, twisted somewhat like a corkscrew at the lower extremities, in order to conduct the thread to the bobbin.

The operation of this machine will now be easily explained. The bobbin containing the roving L is placed in a frame behind, from it the roving passes to the back rollers *g, p*, through a wire eye *o*, fixed in a wooden rod *r*, but has a slow reciprocating horizontal motion, the use of which motion is to make the roving traverse a little on the rollers, to prevent it from wearing them, or wearing the leather too much in one part. The roving being reduced in its passage between the three sets of rollers proceeds through the leader *q* (which is an eye formed of wire fixed in the leader board) to the flier, which twists and lays the thread on the bobbin *m n*, in a similar manner to what has been already described of the flier used in the roving frame. The ascending and descending motion of the bobbin for laying the thread regularly is produced as follows: a wheel in the form of a heart, called the heart-wheel, moves with a regular vertical motion and acts on a roller, which, by means of levers, alternately raises and depresses the bobbin rail M. This rail has pieces of thin wood *x y* projecting from it, which go under the bobbins, and on which pieces they rest and are moved along with the rail; the motion is so calculated that when the bobbin is full of yarn it is swelled a little somewhat into a barrel form; moreover the bobbin (as was described in the roving machine) does not revolve with the velocity of the spindle; but in this it is retarded by friction, which is increased to the requisite

Mechanical
Processes.

Manufac-
tures.

degree by means of washers of cloth or leather; so that the thread by the motion of the flier drags the bobbin about after it, with a velocity equal to the difference between the motion of the flier and the motion of the thread delivered out by the front rollers. The thread is sufficiently strong to bear without injury the drag of the bobbin, and, therefore, as before observed, it does not require the mechanism to regulate its motion which is necessary for the rovings. When the bobbins are full the attendants take them off the spindles. The dexterity with which this work is done, as well as that of the mending the threads, (for which last purpose it is not always necessary to stop the spindles,) always appears extraordinary to those who for the first time witness these operations.

The bobbins when taken off the spindles filled with twists for warps are carried to be reeled, but stocking yarn undergoes the operations of doubling and twisting. This last kind of yarn is softer than common twist, and requires to be more even, because, in a stocking, the whole of the texture at any one part is formed by the same thread, and any defect will make a bar in the stocking, whereas, in cloth, so many different threads cross each other in one place that a defect in any one is seldom perceptible in the cloth. In order to obtain greater evenness, stocking yarn is usually spun from double rovings, wound on the same roving bobbin, and the roving can frame is still used in the preparation for this kind of spinning.

Spinning
with the
throstle.

(995.) *The throstle*.—The throstle is a machine resembling the one last described in the general nature of its action, but it differs from it in this, that instead of heads, each of which may be stopped independently of the rest, the whole of the rollers on one side of the frame are connected, and the whole of the spindles on both sides are driven by means of bands of lists from one cylinder which extends the whole length of the machine. This receives its motion from a belt, and from its axle motion is communicated by wheelwork to the rollers. The cylinder is stopped and put in motion by the fast and loose pulley, but there is an inconvenience in it, that it cannot be stopped for one head without stopping the whole machine. In other respects its advantages are, that it is more simple, consists of fewer parts, and is of course less expensive. It is at present, perhaps, undecided on which side the balance of advantage preponderates.

Mule spin-
ning.

(996.) *Mule spinning*.—We have already, in our historical sketch, given an idea of the general principle of action of the mule-jenny, *i. e.* that it receives the thread from the roving bobbins, passed through rollers to draw it, resembling thus the roller-spinning machine; but instead of receiving the thread when spun on bobbins, it is built in cops on spindles, in which it resembles the jenny; but it differs from both in so far as it stretches as well as spins the thread after a certain quantity has been delivered from the roving bobbin through the drawing rollers. To effect this, the carriage which carries the cops runs backwards and forwards on wheels formed like a pulley on an iron edge or railway, the motion amounting to about four feet and a half; and when about three feet of the drawn roving has been delivered, the delivery is stopped, and the remaining half yard of the carriage motion is employed in stretching the thread, which by this means is obtained much finer than by any other machine which has been yet invented.

This general description will be better understood by

referring to fig. 1, plate lxx. which represents a detached cop G, thread *t*, and bobbin W. The spindle D is fixed in the movable frame above mentioned, while the bobbin W and rollers A, B, C are fixed in their places. Conceive the carriage carrying the cop G to be wheeled up to its nearest position to the rollers, the thread being wound upon the cop. This is now run back at exactly the rate which the rollers deliver the thread from the roving bobbin, being at the same time twisted by the revolution of the spindle carrying the cop; but when the carriage has retreated about two-thirds of its whole distance, the delivery is stopped, and by the subsequent retreat of the carriage the thread is stretched and rendered so much the finer. This being done, the spinner in the hand mule, or the machinery in the self-acting mule, shifts the thread from the point at which it had received its twist to the middle of the cop, and as the carriage is run up, the motion of the spindle is such as just to wind up the length of thread last spun upon the cop; the thread is then again fixed to the end of the cop as before, and the same operation repeated. The shifting of the position of the thread from the position in which it receives its twist to that in which it is wound on the cop, is simply by the action of a wire pressing upon it as shown in the figure by I, H, which turns on the axis I in order to effect this object.

It is impossible in a Work like the present, which pro- fesses to give only a general view of the machinery of Great Britain, to afford sufficient space to describe, at the length which is necessary for a full comprehension of this complicated engine, all the admirable contrivances, adjustments, and proportions requisite for its due action; we shall therefore content ourselves with giving a side view of a mule-spinning engine of the most modern construction, fig. 2, trusting that the reader, by comparing it with the description of its action as above given, will be able to form a pretty correct general idea of its mode of operation.

(997.) *Reeling machine*.—This is an exceedingly simple machine, and the operation is also very simple. It consists simply of a reel with four or six sides, in the form therefore of a square or hexagon, formed by four or six long rods or bars lying horizontally, and which is turned by hand or by machinery, to wind off the thread from the bobbins into the form of hanks, from a row of bobbins placed on the side of the frame. The reeler begins by making all the ends of the threads fast to one of the rails; the reel is then turned, either by the engine or by hand, and when it has made eighty revolutions, which is called a lay, a bell or click strikes, the reel is stopped, and each lay is tied with a piece of thread in order to keep them distinct; and this being repeated seven times, each seven lays form what is called a hank, and the whole is then taken off the reel and the operation repeated. To facilitate the removal, one of the sides of the reel turns on a hinge; this being put down, the hanks become loose and are easily removed.

This concludes the duty of the cotton spinner: the remaining processes belong to the warper, the weaver, bleacher, dyer, and dresser.

In concluding our description of this department of the cotton manufacture, we may be allowed to observe, that in order to make the reader acquainted with the several processes, it has been thought best to illustrate each by the operations on a single thread; which, however, while it renders the conception of the Art more easy, gives no idea of that which strikes a visitor with

Mechanical
Processes.
Pl. lxx.
Fig. 1.

Fig. 1, 2.

Reeling
machine.

Manufac-
tures.

most wonder when he enters the manufactories in which this business is conducted, that is of the extraordinary extent, the triumph of ingenuity, the cleanliness and order which prevail in these several establishments, many of them from five to seven stories high, on floors some hundreds of feet in length, where instead of the single threads represented in our figures, several thousands of such threads are under the continual process of being formed, without labour and without noise; the little girl or boy attendant is at his post to watch the operation of some hundred threads, and whose only business is, when any one by accident breaks, to mend it, or to remove the bobbin or cop when filled, and to replace it. In general, the batting and scutching is carried on on the upper floor, then the carding, then the roving, spinning, reeling, &c., in succession, so that the least possible time may be wasted in removing the material from one machine or process to the next; the whole of the labour being performed by some huge steam-engine or water-wheel in a remote part of the building, the hands which are employed being simply to guide, to stop, or to put in motion this great primum mobile of the whole.

Darwin predicted much which steam has since been made the agent to effect, and we do not think we can more appropriately close our present article than by presenting his lines to the reader.

Where Derwent pours his dusky floods
Through vaulted mountains and a night of woods,
The nymph *Gossypia* treads the velvet sod
And warms with rosy smiles the watery god;
His pond'rous arms to slender spindles turns
And pours o'er massy wheels his foaming urns;
With playful charms her hoary lover wins,
And wields his trident while the monarch spins.
First with nice eye emerging Naiads cull
From leathery pods the vegetable wool;
With wiry teeth revolving cards release
The tangled knots and smooth the ravelled fleece;
Next moves the iron hand with fingers fine,
Combs the wide card and forms th' eternal line;
Slow with soft lips the *whirling* can acquires
The tender skeins, and wraps in rising spires;
With quicker speed successive rollers move,
And these extend while these retain the rove;
Then fly the spokes, the rapid axles glow,
While slowly circumploes the labouring wheel below.

Weaving being nearly the same, whether the cloth be cotton, flax, silk, or other matter, will be best illustrated after describing the several processes by which these different materials are reduced to a form ready to be submitted to this final operation.

Hemp and Flax Manufacture.

Manufac-
ture of
hemp and
flax.

(998.) This manufacture, till of late years, was conducted nearly on the same principles as the original cotton and worsted manufactures; the hemp or flax, after having been prepared, was spun by the wheel and spindle; it was afterwards warped and woven by the handloom, differing only in a trifling degree from the looms used in general for all kinds of cotton and worsted stuff, &c. The great mechanical improvements, however, introduced into the cotton manufacture have led the way to the adoption of similar processes in spinning and weaving hemp and flax, which of course differ in degree, but only in degree, from those we have already described at length under the former article. If we aspired in this Work to describe machines and processes in such detail as to give actual information to manufacturers, it would be

VOL. VIII.

Mechanica
Processes.

necessary to make a distinct article of flax-spinning from that of cotton-spinning; but we do not attempt this task; our object being simply to give to the general reader a tolerably correct idea of these interesting operations, and which differ so little in this point of view from each other as to render a minute description of flax-spinning and weaving unnecessary. The preliminary processes, however, by which the cotton, hemp, and flax are prepared for spinning, are essentially different, in consequence of the different nature of these vegetable productions; this, therefore, requires to be described; and in doing this we shall avail ourselves of a very valuable article on the subject by Mr. Millington, published in vol. xxxii. of the *Repertory of Arts*.

The flax plant is an annual, requiring to be sown with the seeds of the last year's produce from the second week in March to the middle of April. It succeeds best in a free open loam, which is neither subject to too much wet or drought: it is certain of producing a good crop on new ground, and will generally thrive on any soil which is proper for barley or oats. It remains on the ground till the end of July, or the middle of August, when it ripens, and is fit for pulling, (unless it should from circumstances be desirable to keep it for seed only,) and may be succeeded by a crop of wheat or turnips, for which it is an excellent preparation. It may also be sown to advantage with clover seed, which will then succeed it as an after crop. Hemp is a much more rank and coarse plant than flax, growing from six to sixteen feet in height, and is more or less common in all Countries. It is, however, chiefly cultivated in the Northern parts of Europe, whence it is largely imported into England. It thrives well in England; and English hemp, when properly manufactured, is found more compact, strong, and durable than that of Russia. It should be sown about the same time as flax, in a deep, rich, moist soil, on which account the Isle of Ely and the fens of Lincolnshire are particularly favourable to its growth. Like flax, when sufficiently ripe, it is not cut but pulled up root and all, on account of which both these plants leave the soil particularly clean.

The first operation is to obtain the useful fibre from these plants, which is situated between the interior wood and exterior bark of each stalk, and has commonly been obtained by an aqueous decomposition, or by rotting away the wood and exterior bark by exposure to moisture, since the fibre itself (though no doubt somewhat injured by the process) has sufficient strength and durability to withstand it in a great measure. The process of rotting away the woody from the fibrous parts of the plants is one of extreme antiquity, it being noticed in the Sacred writings, and having been used not only in this Country, but on the Continent, from time immemorial; notwithstanding which, it has proved extremely detrimental to the health, not only of the inhabitants but of the cattle of those Countries in which it is carried on to a considerable degree, and is a system which, on this account, it would be highly desirable to abolish. It becomes the source of many pestilential diseases, among which perhaps the malaria, so prevalent in the vicinity of Rome and Naples, may be numbered; besides which, since flax and hemp ripen about the month of August, and require to be submitted to this process as soon as they are taken from the ground, or at least before they dry, the farmer's attention becomes necessary to them, at a time when it is most valuable and can least be

4x

Manufac-
tures.

spared, namely, in the time of, or immediately antecedent to, his corn harvest.

Water-ret-
ting.

(999.) The operation of rotting, or as it is most commonly called, water-retting, flax and hemp, is one of considerable nicety and hazard to the cultivator, on which account it has, in all probability, proved a much greater barrier to the cultivation of these useful plants in England than the alleged exhaustion of soil, or any other cause; for its perfection, and the period when it should cease, depend on several fortuitous circumstances, which may dispose the woody matter of the stem to decompose with greater or less facility. Thus it will be influenced by the strength and vigour of the plant, the moisture or dryness of the season, the temperature of the air during the process, as well as the soil from which the plant was produced. If the operation is carried too far, not only the woody matter, but the fibres also, will be destroyed or injured; and if not far enough, it has generally been thought that the flax will not dress; and thus, after a good crop has been produced, it may be much injured, if not spoiled, in the incipient stage of its manufacture.

The steeping or watering of flax is most commonly performed in artificial ponds or canals excavated by the sides of rivers, and generally about forty feet long, six feet wide, and four deep, a sufficient size to admit the produce of an acre of land at once. Sluices are so disposed that the contained water can at any time be let off, and a fresh quantity of water, which should be soft, admitted. These canals should be exposed to the sun, which assist the decomposition. The fresh gathered flax being tied in bundles or handfulls is carefully placed in these reservoirs, the upper bundles causing those which were first deposited to sink; and in this way each reservoir is filled, but not to such a degree as to force any part of the flax to touch the bottom; and when filled, the whole surface is covered with close hurdles or boards, and sufficiently loaded with stones to cause every part of the flax to be under the surface of the water. In this state it is left, and occasionally examined, to ascertain how far the process of decomposition is completed, which will generally be within a fortnight. The bundles of flax, which have by this time become very tender and difficult to handle, are now to be taken out on boards or trays and removed to the nearest short grass or heath, where they are regularly disposed in rows to lose their moisture, and in which situation they receive an additional preparation from the evening dews and occasional showers completing the decomposition, and at the same time washing away the slime and mucilage with which they are mixed. This last exposure is called dew-retting, and continues, according to the state of the atmosphere, for four or five weeks, or until the flax is as dry as it can be got, of a clean good colour, and all the woody matter which remains is perfectly brittle. The fibre will still retain most of its original tenacity, if the operation has been carefully and skilfully conducted. It is then carried away like hay, on a fine dry day, and deposited in barns, being now ready for the next process, called breaking and dressing, which is the separation of what is commonly called the *boon* or woody matter from the *harle* or useful fibres; and this may be effected in various ways. It is done in mills by machinery, and by hand, and in almost all cases is very effectually performed by a set of blunt iron teeth or breakers fixed upon one piece of wood, and met by another similar set

Dew-ret-
ting.

of teeth fixed to a movable piece, which is worked by the one hand, while the flax in handfulls is introduced between these teeth in various directions with the other hand. This breaks and knocks off the greater part of the wood in small fragments called chaff; and the operation is completed by *scutching* or beating the flax against a smooth post called a scutching post, and also beating it with an instrument somewhat resembling a curry-comb, and called a hand-scutch, by which the few remaining fragments of wood or boon are taken away, and nothing but the long fibre remains; which is now to be hackled or drawn by the hand over a species of comb, having a great number of very sharp, long, and perpendicular steel points upon it, by which any remaining boon and the short fibres or tow are removed, and the long fibres which remain are regularly disposed and ready to pass into the hands of the spinner.

(1000.) *Dry dressing.*—Much inconvenience having been experienced by the retting system, it was long considered a desideratum to effect the same with the plant in its dry state; and at length a process was discovered by Mr. Lee, of Old Ford, in Essex, in 1812, for which he obtained a Patent under the peculiar privilege, granted by Act of Parliament, of having his Patent sealed for the first seven years. The Patent also extended to other processes in the subsequent operations; but valuable as the first part of Mr. Lee's discovery may be, it does not appear that the machines he employed in the subsequent processes, in the first instance, were so successful as he had anticipated. One, which he calls a scraper, consists of a piece of timber supported like a stool, and firmly fixed to the ground at about two feet and a half from it, and laying in a horizontal direction; upon one end of this stool were fixed a few blunt iron teeth, or breakers, about eight inches long, in the direction of the length of the stool, and with their edges pointing upwards; another similar set of teeth were fixed in the same direction, but pointing downwards, at the end of a lighter piece of timber, which at its opposite end was attached by a strong hinge or joint to the top of the stool; and above this a handle to lift it up or press it down by the left hand, while a handful of raw flax was held in the right hand, and introduced between the upper and lower set of teeth or breakers, where it was to be turned and moved backwards and forwards, and occasionally drawn from between the teeth, which were, during this time, kept in a chopping action, and with a due degree of pressure, (so as not to cut or injure the *harle*,) by the motion of the left hand. This machine so nearly resembles the common hand breaker which has long been used in all Countries, that no representation of it is deemed necessary. When the flax had been thus sufficiently broken and scraped it was carried to another, the breaker, very similar in action but rather different in form to the first. In this, one set of breakers or iron teeth were fixed to a short horizontal piece of timber, but instead of pointing upwards they were fastened to one side of it, their length still being in a horizontal direction. This bearer for the breakers had its two ends mortised into two strong upright posts of timber about two feet asunder, the bottoms of which were fixed to the floor, and their tops to the ceiling of the room in which it was to work; the transverse piece carrying the breakers being fixed at such height between them as to be conveniently under the hand of a person standing behind it to work it, and the breakers, which were more in number and smaller than in the machine

Dry dress-
ing. Mr.
Lee's Pa-
tent.

Manufactures.

originally proposed, were screwed into that side of the bearer furthest from the workman. The corresponding breakers were fixed upon another heavy piece of timber, supported by two side timbers very nearly fitting between the upright standards and extending to near their tops, where these were fixed by two screw bolts or round rod of iron passing through the whole four, and serving as a hinge upon which this last apparatus might swing like the batten and swords of a weaver's loom, and to be worked in the same way by a cross bar or handle, near the bottom of which the left hand was to be applied. The flax having passed the first machine was now to be held by the right hand, permitting it to hang down over the breakers and bearer, while the second set of breakers were to be forcibly drawn against it by the other hand; and by a continuance of this operation the fibre at length became freed from all the woody matter and bark, which fell to the ground, and when afterwards passed through a pair of finely fluted rollers was finished and ready for the hackle.

An entirely different process has been since invented and secured by Patent by Mr. Bundy, of Camden Town. For this purpose he employs two machines, a breaker and a rubber. The first of these is for the purpose of separating the harle from the boon as usual, but the process is different. The latter is intended for rubbing and separating the fibres so as to produce it in its greatest state of perfection, and for finally cleansing it before it is sent to the hackler.

Bundy's
Patent
breaking
machine.

(1001.) *Breaking machine.*—This consists of fluted or toothed cylinders, but it varies from other machines of the same kind used for this purpose by the inequality in the depth of the teeth, the play or space which is left between one tooth and another, and in the reciprocating motion of the cylinders combined with a progressive motion, instead of being progressive only, as in the usual practice. The simple manner in which this complex motion is produced displays great ingenuity.

Pl. lxx.
Fig. 3, 4.

This machine is represented in plate lxx. fig. 3, 4; the former is a side view. The framing A in this particular machine is timber, (but it may, of course, be formed of iron.) This serves to support the five breaking cylinders C, C', D, E, E, turning on pivots; C, D, and C' move in brass bearings fixed upon the boards or support B on the two opposite sides of the machine, while E, E merely lie above and between C, D, D, C', and are drawn down to these by two rods, as seen at F, F'; the lower ends of these are joined by a rod or connecting bar, while another rod proceeds downwards, its lower end being fixed by a lower adjusting nut G, near the pin or fulcrum H of the lever or presser H I, which is loaded with a weight J. There is a similar lever on each side of the machine to bear down the four ends or pivots of the two rollers E, E, and the ends of these levers nearest to I are united with a cross bar, by means of which one weight J acts on them both, and is made to press equally by an adjusting nut and screw on each side, like G. K L is a lever placed under the machine, one end of which is attached to the weight J in such manner that, by pressing down its end L, J is raised, and all pressure is instantly prevented between the superior cylinders E, E, and those under them at C, D, C', for stopping the operation of the machine at any time. The breaking cylinders are about 18 or 20 inches in length, and are made of beech or any hard wood, and are all similar to each other in dimensions, and in having breakers, which act also as teeth, extending like projecting plates

their whole length parallel to the axis. These breakers or teeth are formed of thin hoop iron, let about half its width into saw cuts in the cylinders, into which they are driven, and they are retained in their places by iron hoops put on to each end of the cylinders: they are about half an inch asunder, their external edges are well rounded, so as not to cut the flax, and they are alternately long and short, the long or deep teeth projecting about three-quarters of an inch from the cylinder, while the short ones are about half that length. In placing the lower breaking cylinders in their places, care must be taken that they do not touch each other, since their teeth are only to connect through the medium of the two upper rollers which press them. The axis of the roller D is longer than the others, and extends on both sides beyond the frame, and upon each end of it is fixed a cast-iron wheel, by which motion is to be given to the cylinder, and through this to all the others. Both the wheels are of the same diameter, but one is a ratchet wheel, as will be seen in the last figure, while that on the opposite side is a spur or common toothed wheel, as will be seen in fig. 4, which represents such parts of the machine on the opposite side as are essential to its motion, and the same letters of reference are used in both figures to denote similar parts.

The first motion is given to this machine from the iron spindle O, fig. 3, which may be turned by a handle, or by a band and rigger, as at P; it may also be connected with a pair of spur wheels and a fly, as shown in the same figure, to assist its motion. On each end of the lower spindle, if two are used, there is a crank, as at Q, attached to a connecting rod V, the opposite end of which, in fig. 4, is attached to a pall or lever turning on a centre S, so when O or O' is turned, the end of this lever will describe a portion of a circle, shown by the dotted line T A, and will engage with the ratchet teeth of the wheel M, and carry it partly round; while on the other side of the machine, shown in fig. 4, the connecting rod V passes from the crank of O to a toothed segment U, the teeth of which work into the teeth of the upper spur wheel N, fixed upon the opposite gudgeon of the breaking cylinder D. The connecting rod on this side of the machine must be so adjusted in length that in its motion outwards the end tooth of U next to it must be withdrawn out of the teeth of the wheel N, but that when it moves in a contrary direction, or from T towards A, it must move completely in the teeth of the wheel, and not leave them, and of course N at this time is incapable of any other motion but what the segment U also has.

The connecting rod Q V, in fig. 3, must also be so adjusted in length to the pall or gathering tooth S as to make it continue to act upon its wheel M, for the space of one tooth of N, in fig. 4, after the segment U has been withdrawn from its wheel N; and thus, although the motion of U would produce a backward and forward motion of its corresponding wheel N, and the breaking cylinder D, and consequently of all the other cylinders, yet by the after action of S upon M, the roller D and its wheel N are made to advance gradually by the space of one tooth of N for every revolution of O; and thus a slow but regular progressive motion of the cylinders is obtained, at the same time that the vibratory or oscillating motion is going on. The flax is fed or supplied by placing it in handfulls on the feeding trough Z, and pressing it gently between the rollers C' and E, and it is delivered out from between the rollers E and C', at the

Bundy's
rubbing
machine.
Fig. 5.

end of the machine next to L, in a sufficiently clean and divided state to enter the rubbing machine, which will be next described. The superiority of this machine over common fluted rollers needs no comment; since the distance between the teeth and the shake, which is produced by the alternating motion of the cylinders, exactly gives that action which is best suited to break off and disengage the bark and woody matter, which, when dry, is quite brittle, and falls to the bottom of the machine. Once passing the rollers is in general sufficient for either flax or hemp stalks, but the work is rendered more perfect by a second passage through them, which does not at all injure the fibre.

(1002.) *Rubbing machine.*—This is used immediately after the preceding breaking process. Fig. 5 represents a section of the machine, in which *a* is the wooden frame for supporting the other parts of the machinery, *b* the bearers for the three rollers *c, d, e*, disposed as in the breaking machine; but in this case they are only for the purpose of drawing or leading the flax through the machine; (the breaking being presumed to have been already done by the last described, or any other process;) they must be fluted or grooved, or may be made in the same manner as the breaking cylinders, but with the teeth of equal length, much shorter, and of a finer gauge or pitch; *f* is a rigger or pulley, to which a rapid circular motion is to be given; it is hung on a shaft or spindle turning in brass bearings, and fixed to the frame *a*; on the end *h* of this spindle is formed an endless screw or worm, which turns a small wheel *i*, fixed upon the lower end of an iron spindle *k* turning in bearings, and leading, by a bevel pinion at its upper end, to the face wheel *n*, which is fixed on to one of the gudgeons of the fluted or toothed roller *e*, so that whenever the rigger *f* is turned, even with a rapid motion, a very slow motion will be communicated to the rollers *c, d, e*. The most essential part of this machine consists of the rubber boards *o, p, q, &c.*, which are placed at the front of the machine; these are seven in number in the figure, but may be more or less, and are about an inch in thickness; they may be made of beech, oak, or any moderately hard wood. Their edges or sections can only be seen in this representation, but their length may be from eight inches to a foot or more. The board *o* is firmly fixed to the top of the framing *a*, and is without motion, while those marked *p, p, p* are supported upon the two strong cylindrical iron pins *s*, which are firmly screwed into the frame *a*, and pass through holes which fit them in the boards *p, p, p*, so that these last can be moved to a greater or less distance from each other, but are incapable of up-and-down motion. The intermediate boards *q, q, q* are so much shorter as to pass between the iron pins *s*, and admit of an up-and-down motion; for this purpose they are all connected together by an iron link or staple *x*, fixed upon the top of the connecting rod *u*, the lower end of which works upon a crank in the middle of the first spindle upon which the rigger *f* is placed, so that, in every revolution of *f*, the movable boards *q, q, q* are driven upwards and downwards between the more stationary boards *p, p, p*, and the one which is fixed at *o*. The whole of the boards are drawn towards *o* by means of a rod on each of their sides passing through *q, q, q* and *o*, and acted upon at *t* by weights or spiral wire springs, and the whole of the boards are perforated with a slit or mouth from four to six inches long, (according to their width,) and about a quarter of an inch

wide, placed near their tops at an equal distance from the top of each, and nicely rounded off on all its edges. The consequence will be that whenever the crank is in a horizontal situation, all these slits will coincide; but when the crank is down, as in the figure, the slits *q, q, q* (which slits are seen only in section) will be below those in *p, p, p* and *o*, while when the crank is up they will be elevated above them; and thus it will easily be perceived that if the flax, or any other flexible material, is passed through the slits in the boards when they do coincide, and then conducted between the toothed rollers, that while these draw it slowly on through the machine, the boards *p, p, q, q, &c.*, by their rapid up-and-down motion, will effectually rub it and cleanse it from any extraneous matter which may adhere to it, as well as open the fibres. And for the better regulation of this operation, *v* is a treadle or lever near the foot of the attendant, by pressing on which the weight *w*, which depresses the top roller *d*, will be raised, in consequence of which the rollers will cease to draw, although the rubbing still continues, so that its velocity in passing the machine may be correctly regulated at the will of the superintendent.

For the purpose of setting this machine to work in the first instance, and charging it with flax, the tops of all the rubbing boards are movable, and made to separate through the slits which are made in them; for which purpose they are attached at one end by strong hinges, and are fixed down at the other by the thumb screws which are shown in the figure, or by any other sufficient fastenings. It will, however, only be necessary to open them on first setting them to work, since all future qualities of flax to be rubbed may be tailed on that which is already in the machine. The flax is to be supplied by placing it on a perpetually revolving cloth, or feeding table, joined to the end *s* of the machine, and worked by connection with some of its wheels; but this is not shown in the figure, as it forms no part of the invention, and is common in all cotton and flax manufactories.

The average crop which has been produced in England from sowing three bushels of flax or lintseed on an acre of land, is two and a half tons of flax stem, which, when broken and prepared, yields from ten to thirteen hundred weight of harle or flax fit for hackling; and the boon or woody matter which falls through the machine will yield from ninety to a hundred bushels of chaff from the seed, and fit provender for horses or cattle; and from thirty-five to forty hundred weight of chaff from the stem, making a valuable manure, while from ten to fourteen bushels of seed may, in almost all cases, be procured from the same quantity.

(1003.) *Hackling.*—This is the next operation in the preparation of the flax, and resembles in some measure the combing in the woollen and worsted manufactures, the object of it being to straighten the fibres and to lay them parallel to each other. The hackle is shown in fig. 6, 7, plate lxx. It consists of many teeth fixed in a plain, flat board, as seen at A and B. When used, it is firmly fixed to a bench before the workman, who stretches the flax upon the teeth of the hackle drawing it also quickly through them. To persons unacquainted with this kind of work, this has the appearance of a very simple operation which it indeed is, but still it requires a good deal of practice to become expert at it so as to produce a level and fine fleece and without wasting the good material. Our figures only represent one hackle,

tures—
Spinning
flax.

but the workman uses several different ones, of various degrees of fineness, according to the quality of the material on which he is operating.

(1004.) *Spinning flax.*—Till late years flax was spun in single threads by a wheel and spindle, but the improvements which have been since introduced into the cotton trade have been extended also to flax; and in a general view of the case the operations are not very different, although, from the strength and length of the fibre of flax, there is a considerable difference in the degree of draught and power in the several parts of the machinery. One of the finest flax manufactories in the Kingdom is that of Messrs. Marshall and Co., of Leeds, in Yorkshire, and the following is a short description of it, written after being favoured with an inspection of it. The building consists of five floors, and the operators, of which there are some hundreds, are principally girls from ten to twenty years of age. The propelling powers are two seventy-horse steam-engines, one on each side of the building. Each of these drives a series of vertical shafts acting on one shaft, (by means of couplings,) which passes through all the floors; and on each floor there are bevelled wheels on this main shaft which drive various others, lying in a horizontal direction, some of them extending in length to one hundred and thirty feet. From these, and drums upon them supplied with proper straps, all the machinery on each floor is driven, every strap having a fast and loose pulley for putting the machine in and out of gear.

The flax is delivered at the mill, from the grower, in the state we have described, being whole, freed from all its woody particles. In this state it is conveyed from the wagons in which it is brought, by a lifting apparatus, like that of a flour-mill, to the upper floor of the building, where it is opened, and where the process of spinning, or rather the preparation for spinning, commences.

The flax, in this state, is from 26 to 30 or 36 inches in length, and the first step is to take a quantity of it and divide it into three lengths; the part nearest to the root being coarse and strong, the middle part fine and strong, and the upper part still finer, but not so strong. Thus each length being divided into three, and all those of the parts from the bottom, middle, and top being collected into separate heaps, three distinct qualities of thread are to be formed.

The separation of these first lengths into three is effected by a very ingenious machine, consisting of a number of vertical wheels and a centre wheel, furnished with a kind of teeth. The length of flax is held transversely against these wheels, and is passed between two one on either side, while the centre wheel tears it across by separating but not cutting the fibres. This cuts off the bottom part of the length of flax; the remaining part is then submitted to the same process and the middle part cut from the top, each sort being collected in one heap, so as to effect a separation of the three qualities above named. Each division, from what has been before seen, will be, of course, about ten or twelve inches in length. In the next stage, these lengths are fixed in a sort of vice at one end, spread out to a breadth of six or seven inches; several of these are fixed on a sort of revolving drum, at distances of about a foot from

each other, their unsupported ends falling on an internal drum covered with strong cards, the internal drum revolving one way with considerable velocity, and the external in the opposite direction rather slowly, and thereby the lengths of flax are rendered very smooth and straight; they are then dexterously removed by an attendant, generally a girl, and placed with their other side downwards in the next machine and again removed. It should be remarked that these only pass over the upper part of the internal drum; for it is obvious if they passed below, their weight would cause them to fall from, and not upon, the carding roller.

These several operations being performed, the next step is to place these pieces of flax, one just reaching the other, on a feeding cloth, and by the hand slightly to combine their ends: the first end is then passed between two card rollers, or rollers furnished with teeth, which carry the whole forward, while the extreme end passes between two rollers of iron, the latter moving with considerably greater velocity than the former, in some cases 30 to 1, and consequently the flax is now lengthened 30 to 1, and its thickness reduced accordingly. In passing from the roller the flax receives no twist, but comes out flat, and of about the breadth of narrow tape, and is caught in a cylindrical tin can placed below to receive it; when a certain length has been received sufficient to fill the can, a bell rings, an attendant breaks the flax, removes the can, and places another. The flax in the full can is then taken to another machine, where it is again lengthened, and so on to different degrees, according to its intended fineness. After it is properly reduced in the flat state above described, it receives in its last stage a very slight twist so as to reduce it to a round thread. It is then received on bobbins, and is in a proper state for spinning; the process of which differs only in degree from that already described under the article COTTON MANUFACTURE.

In the process above described, where the flax passes over the revolving cylinder, a part of the shorter fibres are detached from the general mass; and this is more particularly the case with the upper part or division of the original length. This is collected and submitted to the operation of carding, similar to the carding of cotton, and in all its subsequent processes is treated in very nearly the same way; this produces a fine but not very strong thread.

(1005.) The linen trade, though not increasing at the same rapid rate which marks the progress of the cotton manufacture, is still in a healthy state, and is stated by Mr. Marshall to have been doubled in England and trebled in Scotland within the last forty-five or fifty years; and the improvements in its machinery have been such that the same gentleman states, in his examination before the Select Committee on Manufactures, that he has, in order to keep pace with them, reconstructed his mill twice within the same period. This must have incurred no inconsiderable expense, seeing that the number of the hands employed in the mill at present amounts to 1229 adults and children.

The following Tables will show the amount of the imports and exports of flax, hemp, and manufactured linen cloth and canvass within the several periods stated in them.

Silk Manufacture.

Early history.

(1006.) The manufacture of silk is generally supposed to commence from that state in which it is received in this Country till it is converted into an article of dress. We are, however, rather disposed to enter upon the business at an early stage, and to trace, as we have done in our other manufacturing articles, the several processes from the first raw state of the material. This seems to be the more necessary here, as it has been for several years a favourite notion with many persons that the silkworm might be introduced into this Country or into Ireland with great advantage.

Silk very scarce with the Romans.

The art of converting the web of the silkworm into articles of dress is of ancient date, the discovery having been attributed to Pamphila, the daughter of Platis. Silk was a very scarce commodity amongst the Romans, having been sold by them weight for weight with gold; and even in the time of Aurelian, in the year 275, it was so expensive that he is said to have refused his Empress a particular request for a silk dress, on account of the price being so great. It was, however, known in Rome as early as the time of Tiberius. At a later date, it is said that immense sums were sent out of the Roman Empire to the further parts of the then known world, for the purchase of a foreign manufacture which employed no citizen or tributary subject; and a great part of the profits arising from so lucrative a commerce fell into the hands of the Persians, the inveterate enemies of Constantinople. In whatever manner, indeed, the traffic had been carried on, so copious an importation of so expensive an article from

so vast a distance must have tended to impoverish the Empire. The Emperor Justinian had long desired to turn this lucrative commerce into a Roman channel, but insuperable obstacles prevented the execution of his design. Those difficulties, however, which all the policy of the Emperor could not remove, were surmounted by the enterprising sagacity of two Monks, who, in the quality of missionaries, had long resided in China. Amidst their religious occupations, they had viewed, with an investigating eye, the manufacture of silk in that Country, the myriads of silkworms, and the mode of their treatment. They discovered that the importation of so delicate and short-lived an insect from so great a distance was impracticable; but they imagined that in the eggs a numerous progeny might be preserved and propagated. Knowing how agreeable the undertaking would be to the Imperial Court at Constantinople, they arrived, after a long journey, at that metropolis of the Roman Empire; and having imparted their project to the Emperor, were, by the liberality of his gifts and the splendour of his promises, encouraged to carry it into execution.

The two Monks having travelled back to China, and by concealing the eggs of the silkworm in a hollow cane, deceived a people, ever jealous of its commerce, returned in triumph to Constantinople with the spoils of the East, having made a greater conquest than either Justinian or his celebrated General Belisarius had ever achieved. Under their directions, the eggs were hatched by artificial heat; the worms were fed by leaves of the mulberry tree; they lived and laboured, and, by the use of proper means, the race was propagated and multi-

Silkworms first brought from China to Constantinople.

Manufac-
tures.

plied. Experience and reflection soon correct the errors incidental to a novel attempt, and in a short time the subjects of Justinian equalled the Chinese in the management of silkworms. From Constantinople this valuable insect has been gradually introduced into all the Southern parts of Europe, and the material produced by it is now manufactured in almost every Country in that quarter of the globe. Thus, in consequence of a singular circumstance in the history of commerce, of which the epoch is assigned to A. D. 552, modern Europe enjoys, at an easy expense, one of the most costly luxuries of the Ancients, which was formerly peculiar to China, and once sold at Rome "*for its weight in gold.*"

Introduc-
tion into
Sicily,
France, &c.

About 1130, Roger II., King of Sicily, established a silk manufacture at Palermo, and another in Calabria, managed by workmen taken as slaves from Athens, Corinth, &c., of which that Prince made a conquest in his expedition to the Holy Land. By degrees the rest of Italy and Spain learned from the Sicilians and Calabrians the management of the silkworm and the working of the silk; subsequently, it was carried into France, about the reign of Francis I.

Broad silk
manufac-
ture in Eng-
land.

We have stated, in our history of the hosiery trade, that silk was first known in England, in a knitted form for stockings, in the reign of Henry VIII., but as early as the reign of Henry VI. silk was used in a woven form as an article of dress; it was also in some measure manufactured at that time in this Country, Henry having silk women, who were, however, probably only employed in needlework of silk. Henry VIII. wore the first pair of silk stockings in England, and in the latter years of the reign of Elizabeth silk stockings were her only wear. Towards the latter end of the reign of James I., *i. e.* about 1620, the broad silk manufacture was introduced into this Country, and proceeded with great vigour and advantage; in 1629, the silk manufacture was become so common in London that the silk throwsters of the city and parts adjacent were incorporated under the name of Master, Wardens, &c., of the Silk Throwsters, and in 1661 this Company employed above forty thousand persons. The revocation of the Edict of Nantes, in 1685, gave another stimulus to the English silk manufacture, by that measure forcing over as emigrants to this Country many of the most ingenious workmen in the trade.

Invention
of the silk-
throwing
mill.

In 1719, a silk-throwing mill was erected at Derby, and from that time to the beginning of the present century various improvements were introduced; but those made since that time, or during, perhaps, the last fifty years, have been very great, and the silk manufacture of this Country is now in a very high state.

The following account of the first silk mill erected in England will be interesting. At the commencement of the last century, a person of the name of Crochet erected a small mill near the present works, with the intention of introducing the Italian method of spinning into this Country. About 1715, a similar plan was in the contemplation of a mechanic and draughtsman named John Lombe, who travelled into Italy to procure drawings and models of the machines necessary for the undertaking. After remaining some time in that Country, and gaining as much information as the jealousy and precautions of the merchants of Italy would allow, he returned with two natives, accustomed to the manufacture, into this Country, and fixed upon Derby as a proper place to establish his works. He

VOL. VIII.

Mechanical
Processes.

agreed with the Corporation for an island, or rather swamp, in the river, 500 feet long and 52 wide, at the rent of about £8 yearly. Here he established his silk mills, and in 1718 procured a Patent to enable him to secure the profits for fourteen years. But Lombe did not live much longer; for the Italians, exasperated at the injury done to their trade by its introduction into England, sent an artful woman over, who associated with the parties in the character of a friend, and, having gained over one of the natives who had originally accompanied Mr. Lombe, administered a poison to him, of which, it is said, he ultimately died. His death, however, did not prove fatal to his scheme; for his brother, and afterwards his cousin, carried on the business with energy, and employed more than three hundred persons. A little before the expiration of the Patent, Sir Thomas Lombe petitioned for a renewal of it; but this was refused, and instead of it, £14,000 was granted him, on condition that he should allow a complete model of the works to be taken; this was accordingly done, and afterwards deposited in the town for public inspection. The property now wholly belongs to the Corporation: the present occupier employs about two hundred and forty hands.

This extensive mill stands upon a huge pile of oak, double planked and covered with stonework, on which are turned thirteen stone arches which sustain the walls. Its length is 110 feet, its breadth 39, and its height 55 feet; it contains five stories: in the three upper ones are the Italian winding engines, which are placed in a regular manner across the apartments, and furnished with many thousand swifts and spindles, and engines for working them. In the lower two rooms are the spinning and twist mills, all of which are of a circular form, and are turned by upright shafts passing through their centres, and communicating with shafts from the water wheel. The spinning mills are eight in number, and give motion to upwards of 25,000 reel bobbins, and nearly 3000 star wheels belonging to the reels. Each of the four twist mills contains four rounds of spindles, about 389 of which are connected with each mill, as well as the numerous reels, bobbins, star wheels, &c. The whole of this elaborate machine, though distributed through so many apartments, is put in motion by a single water wheel twenty-three feet in diameter, situated on the West side of the building.

All the operations, from winding the raw silk to organzining or preparing it for the weavers, are performed here; the raw silk is chiefly brought in skeins or hanks from Piedmont or China. The skein is first placed on a hexagonal wheel or swift, and the filaments which compose it are regularly wound off upon a small cylindrical block of wood or bobbin. To wind a single skein is the work of five or six days, though the machine be kept in motion for ten hours daily, so astonishingly fine are the filaments of which it is formed; the silk thus wound upon the bobbins is afterwards twisted by other parts of the machinery, and is then sent to the doublers, who unite four, seven, or ten threads into one, according to the uses for which it is designed, the fine kind going to the stocking weavers, and the others to different manufacturers.

Till within a few years it was thought that the silk manufactures of this Country stood in need of protection against the French silks, the importation of which was prohibited, but our own manufacturers paid a duty on the raw silk imported. The removal of these restric-

Manufac-
tures.

tions, or at least the modification of them, led to much interesting inquiry and discussion in the British Parliament, but was at length effected; and the result has been, that the quantity of raw silk imported and manufactured in this Country, in the first ten years subsequent to this Act, has been more than double that which it was in the ten preceding years, a triumphant argument in favour of the freedom of trade. This will be seen by the following statement.

Quantities of Raw Silk imported
from 1814 to 1823.

(1007.) *Silkworms*.—Having in the preceding columns given a sketch of the first introduction of silk into Europe, and into England in particular, and shown the immense extent of the silk trade in this Country, we shall proceed now to explain the several processes it has to undergo; but we ought in the first place to give a short description of the little worm which produces in so great abundance this valuable material, and the management of them as practised in those Countries of Europe most celebrated for the production of the raw silk.

The silkworm is an insect not more remarkable for the material it supplies, than for the many forms it assumes before and after its being enveloped in the cocoon or ball it weaves for itself. From a small egg about the size of a pin's head, which is its first state, it becomes a worm or caterpillar of a whitish colour inclining to a yellow. In this state its favourite food is the leaves of the mulberry tree, on which it generally subsists till it arrives at maturity; it then winds itself up in a silken bag or case about the size of a pigeon's egg, and becomes inside changed into an aurelia; in this state it remains without any signs of life or motion, but after some days, if not destroyed, it forces its way out and assumes the form of a moth or butterfly, and after providing for a re-creation by laying several eggs it dies, the eggs thus laid being brought again to life by the natural warmth of the next season, or by warmth artificially procured.

When the silkworm in its caterpillar state is arrived at the size and strength necessary for beginning its work, it makes its web, or that light tissue which is the beginning and ground of its admirable operation; this is the first day's employment; on the second it forms its folliculus or ball, and covers itself almost entirely over with silk; on the third it is quite hidden, and the succeeding days it thickens and strengthens its ball, always working from one single end, which it never breaks, and which is so fine and so long that those who have examined them attentively have found or stated the length of line in one ball to measure six English miles. In ten days the work is finished and the ball or cocoon is in its perfection; and when carried on in the open air, they have now to be taken down from the branches of the mulberry trees whereon the worms have hung them. This operation requires care and judg-

Manufac-
tures.

ment, for some worms working quicker than others, some are ready before others, and the forwardest, if left too long, would force their way out, which is best avoided.

This being done, the finest and strongest balls are preserved for breeding, and the rest are carefully wound. The winding is effected differently in different places, which will be described as we proceed. If there be no more than can be wound at once, the balls are laid for some time in an oven moderately hot, or they are otherwise exposed for several days successively to the greatest heat of the sun, in order to kill the insect, without which it would not fail to force its way out; and although it is not true, as is sometimes stated, that the silk is thus eaten away, yet the balls of this kind will not unwind so freely as those in which the insect is destroyed. The balls are of different colours, particularly those of different districts, but the most common are yellow, orange, a slight green, and flesh colour. We have spoken above of the worm fed in trees, but a large proportion of European raw silk is produced in chambers or sheds, either by parties employing certain amounts of capital and carrying on the business on a large scale, or by the peasants in their cottages. In these cases the worms are tended and fed by hand with leaves stripped from the mulberry tree, and they may thus be reared in Countries otherwise too cold for their production. It has been a favourite idea with many persons, ever since the time of James I., to introduce the silkworm into this Country or Ireland; James himself was a great advocate for making the attempt, and, indeed, it has been frequently made with some appearance of success. Recently, Mr. Murray, who had spent some time in Italy, and took particular notice of the management of the worm, has again called the attention of the nation to the subject, and has given a very interesting account of a Work by Count Dandolo, in which all the circumstances attending the treatment and produce of five ounces of ova are minutely traced. There are also statements respecting trials of different kinds of food, &c. We select the following particulars, which were given by the author in vol. ii. of the *Edinburgh Journal of Science*.

For each ounce of ova, 1084 pounds of leaves have been taken from the tree. Mechanical Processes.

The silkworms, from five ounces of ova, have consumed the above 5420 pounds of leaves, and each produced 401 pounds of cocoons.

For each pound of cocoons there have been consumed about 13½ pounds of mulberry leaves.

The Temperature required for the Production of Silk Worms from the Ova, anterior to 23d May, 1814.

1814. Month.	Internal Temperature.	External Temperature.
	Fahrenheit.	Fahrenheit.
May 11	63° 50'	50° 26'
12	63 50	45 50
13	63 50	45 50
14	63 50	45 50
15	65 75	47 75
16	65 75	52 25
17	68 0	50 0
18	70 25	50 0
19	72 50	50 0
20	74 75	52 25
21	77 0	52 25
22	73 25	54 50
23	81 50	52 25

The external temperature was ascertained at five o'clock every morning, from a Western exposure.

During the thirteen days in which the silkworms were developed from the ova, 134 pounds of food were consumed. The pound of 28 ounces is to be understood, or two pounds Troy, equivalent to 0.7625 kilogrammes of France.

The following is the daily decrease in weight of 1000 ounces of cocoons in a room, the temperature of which is from 70° 25' Fahrenheit, to 72° 50' Fahrenheit :

Days.	oz.	oz.	Days.	oz.	oz.
First	1000		Seventh	960 less 6	
Second	991 less 9		Eighth	952 less 8	
Third	982 less 9		Ninth	943 less 9	
Fourth	975 less 7		Tenth	934 less 9	
Fifth	970 less 5		Eleventh	925 less 9	
Sixth	966 less 4				

So that the 1005 ounces have lost in ten days, during the mutation, 75 ounces. There is a gradual declension for the first five days inclusive, and a regular gradation for the five last days.

Eight ounces of ova have lost in five days, in weight, 100 grains; in eight days 360; and in ten days 440.

Six ounces of ova have lost in five days, in weight, 86 grains; in eight days 178; and in ten days 248.

Five ounces of ova have lost in five days, in weight, 60 grains; in eight days 168; and in ten days 216.

Four ounces of ova have lost in five days, in weight, 80 grains; in eight days 181; and in ten days 224.

Each grain contains about 68 ova, and an ounce weight 39.168 ova. The *ancia Milanese* contains 575 grains. The above number is to be understood of *fecundated* ova. Those which are badly impregnated contain 43.080, and are of a reddish colour; and of those not at all impregnated, and of a yellowish tinge, there are in the ounce 44.100.

Manufac-
tures.

The expense of the contingencies of the five ounces of crop, in 1814, are thus calculated by Count Dandolo.

Cost of 5 ounces of ova	15
Wood for fuel	11. 3
5500 pounds of leaves of mulberry, at 7 lire per 100 pounds	385
Expense of gathering the leaves..	96. 5
100 pounds at 32 soldi	16
Supplement	4. 10
Supplemental paper	4
Oil for light	9
Preservation phial	1. 10
Daily labour	100

Lire Milanese	642
Interest, &c. on capital	90

Total expense	732
401 pounds of cocoons obtained, which, being sold at 78 soldi per pound, produced	1563. 18

Net profit, lire

Note.—A *lira Milanese* is equal to about 8d., and there are 20 soldi in a *lira Milanese*.

The calculation, as above, includes not only interest on capital, but a valuation on the mulberry leaves, which is about one-half of the total expense.

The Augmentation and Diminution of the Silkworms in Weight and Size.

Increasing Progression.	Weight.
100 ova weigh about	1 grain
After the first change about	15
„ second „	94
„ third „	400
„ fourth „	1628
„ fifth „	9500

Increasing Progression.	Size.
The ova in the first instance about	1 line
After the first change, length about	4
„ second „	6
„ third „	12
„ fourth „	20
„ fifth „	40

Note.—In the 30 days, the silkworm has increased in weight 9500 times; and in 28 days, the animal has augmented in size about 40 times.

The French line is equal to 1.67 line English, calculating 100 lines English to the inch.

Decreasing Progression.	Grains.
100 silkworms, at their greatest size, weigh about	7760
100 chrysalis weigh	3900
100 females weigh	2990
100 males weigh	1700
100 females, after the ova are deposited	980
100 females naturally dead, and the eggs or ova deposited, &c.	350

In the space of about 28 days more, the silkworm has diminished in weight about 30 times. Thus the length of the silkworm, from the time of its greatest increase to the moment it is converted into the chrysalis, has diminished about three-fifths.

The chrysalis is the intermediate state between the worm and the winged insect.

Space occupied by each Ounce of Ova cultivated.

In the first age an area of square braccia	4
„ second „	8
„ third „	19
„ fourth „	45
„ fifth „	100

Note.—The *braccio di Milano* is divided into 12 ounces or inches, and corresponds to 5.95 palms, which may be calculated at 22 English inches nearly.

Amount in Weight of Mulberry Leaves consumed by the Silkworms. For every Ounce of Ova there have been consumed 1078 pounds of Leaves, divided as follows, viz.

	lbs.	Leaves, &c., left destroyed unused.	lbs.
First age eaten ...	4	First age	1
Second „ ...	12	Second	2
Third „ ...	40	Third	6
Fourth „ ...	120	Fourth	18
Fifth „ ...	732	Fifth	68
	908		95

In the course of the management of the silkworms, the 1073 pounds of leaves from the tree (from evaporation, &c.) will have lost 70 pounds.

Note.—There have been devoured by the silkworms about 515 pounds of pure mulberry leaves. The 1073 pounds of leaves, as taken from the tree, will yield 80 pounds of cocoons, calculating from one ounce of ova.

(1008.) The following is a more general view of the production of silk in the different Countries and districts in Europe where this business is conducted on the largest scale, for which we are indebted to Mr. Felkin.

At present, European silk may be properly classified as produced in the following districts, viz., mountainous France, the plains of Dauphny, &c., Piedmont and Nice, the Milanese, Tuscany, the Roman States, Neapolitan States, &c. In inquiring into the production of raw silk, the cultivation of the mulberry tree, so indispensable for the food of the worms, forms a particular object for investigation, the care of the worms is another, then the amount and quality of their produce, and the winding the cocoons.

The rose mulberry is almost the only kind planted throughout Europe for producing the food for silkworms. In its culture, the principal objects are the quality and quantity of its leaves; the coldest districts seem from various causes to be the most remarkable and appropriate to its growth, whether as regards care and skill in planting and pruning, or the relative quantity and quality of the leaves produced. The greatest amount of success has attended the cultivation of the mulberry in mountainous, dry, and barren districts; the following proportion being given as near the truth in reference to the produce of the mulberry in the following European silk districts.

A given number of trees produce in

	lbs.	Relative nutriment of trees in different soils.
The mountains of France	100	
Piedmont and Nice	85	
Plains of France	75	
Milanese	75	
Tuscany, Roman States	65	
Neapolitan States	60	

Of these, the former two, i. e. mountains of France

Manufac-
tures.

and Piedmont, produce leaves in the highest degree nutritious. Those of the plains of France and the Milanese are less nutritious by ten or fifteen per cent., and those of Tuscany and Naples by from twenty to thirty per cent.

A certain proof of the difference in the quantity of leaves produced by trees in these respective districts is found in the greater or less number of trees necessary to feed a certain number of worms; and we have a proof of difference in the quality of leaves, in the greater or less weight consumed producing a certain quantity of cocoons. The causes of these differences probably are, that trees succeed well in proportion to the purity of the air; the soil on which they are grown being more or less light and dry, and kept free from weeds or other vegetable matters. Each plucking of the leaves should be succeeded by careful pruning; and as standard trees are preferable on account of longevity, productiveness, and the greater adaption of their leaves to the health of the worms, they should be kept quite open in the centre of the head of the tree, by which mainly they are preserved from disease.

Human labour and skill are most easily obtained and applied to this cultivation, following the gradation above marked out in the respective silk districts. France had, in 1825, sufficient young mulberry trees planted to double its supply, if necessary, in ten years; Piedmont might increase one half in ten years, and the Milanese the same from trees already planted; the rest of Italy was stationary. It is found, in France, that the grafting on the wild stock tends much to the superiority of the leaf, both in respect to the health of the worm and the quantity of the silk. The two most fatal diseases with which the worms are affected are called the *gras* or the *jaune*, and may generally be traced to gross, overheated, or damp leaves.

Proportions
of food and
silk pro-
duced.

For every 1,000,000 pounds weight of raw silk produced in France, it is calculated that 250,000,000 pounds weight of leaves are consumed, and that 5,000,000 trees, of the average age of thirty years, are stripped to furnish them. In breeding silkworms, the essentials are, a sufficient supply of heat, fresh air, and recently gathered dry mulberry leaves. European recoils succeed best in the hands of persons who invest money in them for the sake of profit; but the largest proportion of the worms is fed by peasants on their own account, as an additional means of support; and, owing to the little space their dwellings afford, they only get to spin on an average, upon the scale of an ounce of eggs hatched, 33,000. In mountainous France, in which one-half are chamber recoils; and in these for each ounce hatched, 20,000 worms spin 85 pound cocoons, and one-half cottage recoils, in which 12,500 worms spin 55 pound cocoons.

In Piedmont, in which one-fourth are chamber recoils; and in these, for each ounce hatched, 18,500 worms spin 80 pound cocoons, and three-fourths cottage recoils, in which 11,500 worms spin 50 pound cocoons.

In the plains of France, one-fourth are chamber recoils; and in these, for each ounce hatched, 13,500 worms spin 60 pound cocoons, and three-fourths cottage recoils, in which 10,500 worms spin 45 pound cocoons. In the Milanese, one-fourth are chamber recoils; and in these, for each ounce hatched, 16,500 worms spin 70 pound cocoons, and three-fourths cottage recoils, in which 10,500 worms spin 45 pound cocoons. In Tuscany and Roman States, one-fourth are chamber recoils; and in these Countries, for each ounce

hatched, 11,500 worms spin 50 pound cocoons, and three-fourths cottage recoils, in which 9300 worms spin 40 pound cocoons. In the Neapolitan States, all cottage recoils, in which 9200 worms spin 40 pound cocoons.

Mechanical
Processes.

The price of cocoons is highest in those Countries where the recoil is best. The respective prices of the recoil, in 1825, (which was below an average one,) for ordinary fair parcels, Doppions and Chiques inclusive, were

Different
prices of
the cocoons.

	s.	d.
Mountainous France, for 16 ounces English	1	6
Piedmont, plains of France, and the Milanese, ditto	1	4
Tuscany, Roman States, and Naples, ditto	1	0
Calabria, ditto	0	10
Spain, ditto	1	2

The weight of silk produced in the year 1825, in the respective districts, and the average prices of fair silks, were as follows:

	lbs.	Mean Price per lb.
Mountainous France ..	750,000 of 16 oz. English, at	24s.
Piedmont	1,440,000	23
Plains of France	850,000	20
Milanese	2,650,000	18
Tuscany	100,000	16
Roman States (supposed)	500,000	17
Ditto Eastern ditto ...	500,000	24
Naples	100,000	18
Calabria	300,000	12
Spain, amount unknown.		

In consequence of new light being thrown upon the management of recoils within a few years, those of mountainous France and of the Milanese have been much improved, and are increased full one-third; those of Piedmont and of the plains of France are stationary: the production of silk in the other districts seem to have somewhat declined, probably owing to political causes. In the reeling of cocoons, care and skill produce the chief difference in the value of the silk; it is, however, to be remarked, that the best cocoons are certainly the Piedmontese; those produced in the mountains of France are scarcely inferior; the other districts produce them of nearly equal quality to each other, but all are inferior to the above. The excellence of the silk reeled in the higher districts of France has obtained for it a great demand in the French market, and this would probably be much larger were the English market open to its sale. The nerve of Piedmontese silk, and that of Fossombrone, has mainly contributed to keep up their price; this quality is, however, shared by the silk produced in all mountainous districts. The high priced silks are principally reeled in filatures, the lower by the peasantry.

Improvements have taken place in reeling cocoons in the higher parts of France within the last twenty years which surpass the progress made in the previous two centuries; these consist principally in the increase of filature reeling, and in carefully sorting the cocoons, and giving regular instruction to the hands. The reels are generally turned by power, and the water is heated by steam, double threads are avoided, and thus regular fine silks are produced with great advantage. Reeling is somewhat improved in the Milanese, by the application, to a certain extent, of the same means as in France. Improvements in the manner of cultivating the trees have been generally and effectively introduced in the mountainous districts of France, and in Piedmont, where they present a striking contrast to the

Manufac-
tures.

ill-conditioned standard trees of Dauphiny, Lombardy, and the Southern Italian States.

The peasantry engaged in breeding silkworms in the various districts of Europe have as yet made but little progress in improvement, but the larger chambers often present great skill and attention to the requisite details; the rooms built for this purpose are now larger, more airy, and arranged so as to produce a great circulation of air suddenly. Great cleanliness, and giving the worms dry food, have been attended with the happiest results; the peasantry living in the highest ranges of the hills often bring down for sale excellent samples of cocoons.

Progressive
increase of
silk in
France.

The progress of the production of silk in France has been considerable.

In 1789 it was 1,000,000 pounds.

In 1820 „ 1,350,000 „

In 1825 „ 1,600,000 „

The consumption, in 1825, was 3,000,000 pounds, which quantity, and of sufficiently good quality, she may probably produce by the year 1840, if necessary. Prejudices are very general on several important points; as for instance, in favour of lopping off large branches from trees, instead of small and frequent prunings; of letting the trees grow in grass meadows or amongst corn, without digging around the roots, as is necessary six or eight times during the year. The loss in leaves from these causes has been estimated by some so high as a third of what might otherwise be obtained. The poor people often suffocate the worms, and generally those they preserve are very much weakened by being subjected to close heat; it is difficult to make them understand that confined air may kill the insects at seventy degrees, but that they may remain healthy if the air be in circulation, though the actual heat be ninety degrees; this accounts for a large proportion of the extra loss in the peasants' breed of worms. They conceive they gain by reeling their own silk, but so much are they mistaken that there is no doubt they lose ten per cent. at least. The reeler by profession does not gain more than from ten to fifteen per cent. after he has paid all expenses, and runs considerable risks, although he produces from similar cocoons a far superior article.

Season for
reeling.

The owners of filatures have a great prejudice against reeling longer than during July, August, and September; certainly this period might be considerably extended without injury to the cocoons or the silk, and with great advantage to the persons employed. It is possible also to reel at less speed than is usual, if increased care and time be desirable. But the most important error, and one that has hitherto universally prevailed, is that which supposes all coarse reeled silks must be necessarily irregular also. It is just as possible to produce a coarse even thread as a fine one; and the advantage gained by reeling even thick silks must be apparent to those who know the waste and expense attending throwing fine silks to be used for various purposes, where even thick silks are necessary, and which must be superadded to the increase of cost of reeling fine silks.

Manufac-
ture.

(1009.) *Manufacture of silk.*—Having in the preceding pages given as complete an account as our limits will admit of the management and produce of the raw silk, it remains for us now to trace it through its several operations till it is in a state fit for the weaver, as we have done in the other materials already treated of.

Reeling.

Reeling the silk from the cocoons.—The cocoons become an article of trade as soon as the insect inside has

been killed by exposing them to the heat of the sun, or of an oven, or to the steam of boiling water: they are now to be wound. To effect this the balls are thrown into a vessel of water, having a charcoal fire beneath to preserve the water always of a proper temperature, and near this vessel is placed the reel on which the silk is to be wound. In this operation, it is to be understood that the ends of several cocoons are joined and reeled together out of the vessel of hot water above described, which softens their natural gum and causes the fibres to stick together in the form of one thread, and as often as a thread of any single cocoon breaks or comes to an end its place is supplied by a new one, so that, by continually keeping up the same number, the united thread may be wound to any length; these joinings are not made by a knot, but the new end is simply laid on the compound thread, to which it will adhere by its gum. In the commencement of the operation, after the cocoons have lain a few minutes in the hot water to soften their gum, the person by whom this work is done stirs up or brushes the cocoons with a whisk or birch rod cut rather short, and to this the loose threads of the cocoons will adhere and the ends are thus drawn out of the water; they are then taken, commonly four together, as twisted with the fingers, then passed through an eye made of wire, and thence to the reel; four other ends are in like manner passed through another eye to the reel so that two skeins are reeled at the same time; one person, commonly a child, turns the reel, and the other, generally a woman, attends to mending the threads. The reel is so constructed with cog-work that it has in its revolution a slight lateral motion, so that the thread of one revolution does not overlay the other, for if it did the natural gumminess would cause these threads to adhere: this lateral motion is such as to extend the breadth of each skein on the reel about three inches, by which time the gum is sufficiently dry to prevent the sticking; it then, therefore, traverses back again, and thus the work proceeds till the skeins are completed. All kinds of silk which are simply drawn from the cocoons by the reeling are called raw silk, but are denominated fine or coarse according to the number of fibres of which the thread is composed.

Mechanical
Processes.

(1010.) *Winding.*—In the state last described the raw silk is generally imported into this Country, and the first process it undergoes here is the *winding*, that is transferring it from the form of skeins on to bobbins. This process was formerly done by hand, and the machine carried four or more reels and as many bobbins, on which the silk was received, but at present, in our large silk mills, all these operations are performed by machinery; a number of reels extending to a great length, lying horizontally, receive as many skeins of silk, and on each side is an equal number of bobbins, the whole of which are put in motion by the machinery driven by the steam-engine or other first mover. The winding requires the unwearied attention of children to mend the threads that break, as well in this process as in the next, and it is by no means uncommon in our largest mills to have six or eight hundred or a thousand of these little operators busily employed. The old reel or swift consisted of four double arms so as to form a square, with a contrivance to stretch the skein to a proper tightness; but the modern swift has six single arms instead of four double ones, these arms being small flat tubes made to contain the stems of wire forks which receive the skeins instead of the bands in the common swift. These forks admit of being drawn out from the tubes

Winding.

Manu-
factures.

till the swift is sufficiently enlarged to extend the silk to its proper tightness; and instead of the weights formerly used in the old machine to keep the thread to its proper tightness to be received on the bobbin, this is in these done by small springs for the purpose.

Doubling
and tram-
ming.

(1011.) *Doubling and tramming.*—The silk being by the preceding process transferred from the skeins to the bobbins, the next operation is that of tramming, which consists in laying two, three, or more threads together prior to the throwing or organzining. This machine is very variously constructed, but the conditions absolutely essential in all are the following: first, that the silk may pass off easily and without entangling from the delivering bobbins; secondly, that a small and equal degree of tension be applied to the threads as they pass from the delivering bobbins to the receiving one, so that the compound thread shall be perfectly even, which would obviously not be the case if one of the component threads were quite loose while the others were drawn straight; thirdly, that the receiving bobbin cease to revolve as soon as any one of the component threads happens to break, (an accident which not unfrequently occurs,) as without such contrivance a thread would be produced of variable thickness, from the casual omission of one or more of the component threads.

The operation of tramming, in some of the best constructed mills, is performed in the following manner.

The delivering bobbins (varying in number from two to four, according to the intended thickness of the compound thread) are placed upon as many vertical spindles, the vertical position allowing the thread to quit the bobbins without any revolution or motion of the bobbins themselves. Some way above the bobbins the threads pass singly between two horizontal slips of cloth or felt, which, by their friction, give at the same time a certain degree of tension to the threads, and clear them from dust or any other light matter. Each thread then passes through the eye of what is called its drop wire; whence they all converge towards and unite in the eye of the guide wire, from which the compound thread is delivered and distributed on the surface of the receiving bobbins as it revolves.

Each drop wire consists of a piece of wire turned up so as to form a right angle, of which the vertical leg is about two inches long, and is terminated by an eye through which the thread passes, and the horizontal leg is about four inches long, terminating likewise in an eye, through which passes a pin connecting all the drops, and thus forming a pivot on which each is capable of moving freely. Each thread, in passing through the eye of its drop wire, slips down a little, and, being in a state of moderate tension, supports it at the elevation of half an inch or more above the position to which it would otherwise descend. When, therefore, a thread breaks, its drop wire immediately falls, and strikes on the edge of a wire frame moving on a horizontal pivot, and so adjusted that the weight of the drop wire immediately inclines downwards that side which it touches and consequently raises the opposite side. To this opposite side a tail wire is attached, which, when raised, catches on a kind of ratchet wheel fixed on the same spindle as the revolving bobbin, and consequently stops it. The broken thread being repaired, it is again passed through the eye of the drop wire, and supports it above the frame; the opposite end of the frame then becomes preponderant, the tail or stop descends out of the way of the ratchet wheel, and the revolution of the receiving bobbin again commences.

VOL. VIII.

(1012.) *Throwing or twisting.*—The bobbins being thus filled with compound threads, the next process is that of twisting them into one. This machine, as well as the doubling and tramming, winding, &c., has been much varied in its form of late years; in some machines the bobbins are furnished with a flier and made to revolve by an endless strap which drives a great many bobbins at the same time, by which the twisting is effected, the thread as twisted being received on a long horizontal reel whose revolution is so regulated as to allow of a proper twist being given to the silk. In others, the silk is twisted and received on other bobbins. It would be useless to attempt to give descriptions and drawings of all the various plans which the ingenuity of our silk manufacturers have introduced into their mills of late years. We shall therefore content ourselves with giving one entire process from the winding to the throwing, as described by Mr. Badnall, of Leak, in Staffordshire, for which he obtained a Patent in 1825. See plate lxxi., Silk Manufacture.

Here fig. 1, 2 represent a side view and plan of a winding machine. A, A are swifts, on which the hank of silk is placed or stretched in the ordinary manner. B, B are pulleys firmly attached to the axis of each swift; with a groove in them from which a band passes round the smaller pulley C C. Motion is communicated from these by the driving wheels D, D, which are themselves put in motion by any first mover.

The periphery of the driving wheels and pulleys coming in contact with each other, when the former are set in motion, the latter must revolve also, and, consequently, the swift also which bears the silk. Upon the periphery of the driving wheels are placed small wheels E, E, to which the spindles are attached which carry the bobbins upon which the silk is intended to be wound. This is best seen in fig. 2, where *a, a* represent the bobbins, F, F, fig. 1, are levers which act under the pivots of the spindle wheels E, E, upon any tension being applied to their longer arms, the fulcra being placed as near as convenient to the point where the shorter arm of the lever comes in contact with the pivots of the wheels.

On power being communicated to the driving wheel, motion, as already explained, is given to the pulley C C, B B, and to the small wheels E, E, which carry the bobbins. The result is, that a revolution of the swift and a corresponding one of the bobbin is effected, and so proportioned that the latter receives the thread at exactly the rate at which it is delivered from the former. To regulate, however, any variation caused by the increase of silk on the bobbin as it becomes filled, and its consequent increased bulk and decrease of the hank or skein, the levers F, F are brought into action; for on the slightest increased tension of the thread or threads which pass over the levers, the pivots of the wheels E, E are immediately acted upon, and are consequently raised from contact with the driving wheels D, D, and the speed of the bobbin retarded until a further supply of silk is given off from the swift. It is proper to state that the silk is made to pass over the glass rail H H, and thence over the levers F, F through the eyes or guiders G, G, and thence to the bobbins.

Fig. 3 represents another arrangement intended for effecting the same object, and for which, in many cases, it is supposed to be preferable. Here A is the driving wheel, B the receiving bobbin, C the compensating lever; but instead of employing a swift, the silk is

Mechanical
Processes.
Throwing
or twisting.
Pl. lxxi.
Fig. 1, 2.

Manufactures.

stretched on two cylinders D, E, of tin or other material, technically called *rise heads*; the upper one D, resting on the driving wheel, is acted upon in the same manner as the band wheel C in the former figures. It will, therefore, be readily seen that the silk being stretched on the cylinders, and the upper one put in motion by the driving wheel, it will revolve in the manner of an endless strap or band, giving off its thread to the receiving bobbin, as shown in the figure.

Fig. 4, 5.

The lever C acts in this arrangement exactly in the same manner as already described, but, to prevent the thread from getting entangled, it is made to pass over a plate of tin or other suitable material, F F, of the same breadth as the skein of silk, its sides being turned up to prevent the silk running off; this is shown detached in fig. 4.

The lower cylinder E may be moved to a greater or less distance from the upper D to accommodate that distance to the opening of the skein of silk; this is effected by the screw and slide G. In order to allow the plane F F to be accommodated likewise to the cylinders, it is divided into two or more pieces of any length, which being placed as at *a, b, c, d*, one under another, admit of any degree of extension short of the united length of the pieces of which it is composed.

In fig. 1, *x* represents a small ratchet, the object of which is to prevent the silk from being wound off again from the bobbin in case of its sticking in the skein; this is seen more clearly in fig. 5.

Doubling machine.
Fig. 6, 7, 8, 9.

(1013.) The *doubling machine* is represented in elevation and plan in fig. 6, 7. Any number of bobbins, on which the silk has been previously wound, are placed in an upright position on any suitable frame or board B B, and, according to the number of threads wanted to be doubled, such number are placed between the rods or bars C, C, C, (which are of glass,) and separately conveyed through small loops or eyes of the wires *a, a, a*, and thence through the guide loop or eye *b* to the receiving bobbin D. The glass rods or bars C, C, C, are fixed in an upper and lower frame, the upper one movable on hinges *c, c*, so that, instead of passing the silk under one bar and over the other, the same is effected by the top frame being raised, and, when the threads are passed over the lower frame, let down again, which falls upon the silk and forms angles or curves resembling those shown in fig. 8, by which means sufficient friction is produced to lay the silk with proper tightness on the bobbin D, and to keep the loops or eyes of the wires *a, a, a* elevated as long as the threads continue whole. E is a lever exactly balanced, one end of which has a plate of tin attached to it, and this plate is fixed exactly under the wires *a, a, a*, so that if any of the said wires, by the breaking of the thread which elevates them, should fall, the end of the lever upon which it falls would immediately preponderate and the opposite end be raised, thereby stopping the motion of the receiving bobbin, in a manner similar to that mentioned in our preceding general description. Fig. 9 represents a bobbin with a circular rim of polished metal on its top, the object of which is to prevent breaking the threads, which frequently occurs where the common guider or fly is used.

Spinning and doubling.
Fig. 10, 11, 12.

(1014.) *Spinning, doubling, and throwing*.—Fig. 10, 11 are a side and front view of the improved machine for spinning, doubling, and throwing at one operation, which was patented by Mr. Badnell in 1823, and of which the following is the specification.

“Fig. 12 represents a bobbin and guider or flier, as commonly used, to which guider I chiefly attribute the greatest portion of the waste made in the throwing of silk, the causes of which are obvious. The guider or flier A moves loosely on the spindle; to this spindle the bobbin B is firmly attached. Considerable friction and strain is therefore produced on the silk by the power required to draw round the guider or flier A, independently of the angular position which it necessarily takes in being drawn off the bobbin. To counteract this, therefore, the circular metallic rim, represented in fig. 9, is substituted, whether attached to the bobbin or placed loosely on the top of it.

“In the figs. 10, 11, A, A are bobbins upon which the silk has been previously wound or doubled, according to the description of the manufactured article required; at the top of these bobbins are either attached, or placed loosely, the circular rims B, which are called waste preventers, and which are made to extend about one-fourth of an inch beyond the circumference of the bobbin. C is a rectangular bar of wood or metal covered with woollen cloth, or any other material capable of producing friction. Over this bar, and once or more round it, the ends of the silk are taken from the bobbins A, A, and conveyed through the loops or eyes D, D through the rollers E, E to the receiving bobbin F. Motion is given to the spinning spindles G, G, and to the throwing spindle H, by an endless strap, band, or chain I I, passing between their whorls or stockings, as described in the drawings, which strap is actuated by a drum or cylinder in the usual manner. It is evident, on reference to the figure, that if the strap be set in motion, the spindles G, G will be revolving in an opposite direction to the spindle H; and if the rollers be also set in motion, which motion is regulated so as to suit the exact quantity of twist the kind of silk requires, the silk will be drawn from the bobbins A, A, and received on the bobbin F, in the usual manner of cotton spinning. The bobbin F being loose upon its spindle, and the flier attached fast to it, a sufficient friction for all necessary purposes is produced by passing the silk round the covered rail or bar C. By this contrivance the guider A, as described in fig. 12, is rendered useless, and consequently the breakage of threads very materially diminished. Independent of the above great advantage arising from the use of the ‘waste preventers,’ they allow a very great increase in the speed, to which the guiders commonly in use were an insurmountable obstacle, in consequence of the centrifugal action being so great as to cause an extension of the wires when they very frequently came in contact with each other; and this happened particularly in this method of throwing, when it was necessary to have the receiving or throwing spindle as close as possible to the giving off or spinning spindles. In case the thread or threads from either of the spinning bobbins A, A, which unite at the rollers, should break, a cutter, as represented in fig. 13, is provided, which is placed on the lower part of the frame K K, which frame also supports the rollers, and by passing the two ends of the silk over the cloth bar C C, then crossing the threads round each other, and then passing them through the upper loops or eyes D, D, they maintain, as long as they remain unbroken, a situation as shown in fig. 14; but as the points I, I of the cutter, as shown by fig. 13, are two small pieces of sharpened steel, on the breaking of either thread, the remaining one being liberated, will immediately come in

Fig. 13, 14

Manufac-
tures.

contact with one of the said pieces of steel and be instantly cut.

"According to the diameters of the whorls or stockings which are fixed upon the giving-off spindles G, G, and the receiving spindle H, will be the proportion of twist or spin between them, and according to the speed of the rollers will be the twist or spin given to the united threads. It is here necessary to state that, by means of the above-described cutter and circular metallic rim, with the cloth friction bar, the two operations of doubling and spinning may be performed at the same time. The mode of doing this will be easily understood by referring to fig. 10, and supposing the rollers E, E to have their place supplied by the ordinary receiving bobbins, while the receiving bobbin F of the mill is taken away all together. If, then, the two threads are carried from the two spinning bobbins A, A, in the manner described in the plate, to the receiving bobbin that has taken the place of the rollers E, E, they will be gathered on that bobbin, having been first spun by the revolutions of the two bobbins A, and thus doubling and spinning in one operation.

"In fig. 1, 2, I claim any means of giving motion to a swift, rise head, or any other reel upon which silk may be placed for the purpose of being wound on to the receiving bobbin at the same time, in conjunction with a compensating apparatus, or any imitation thereof whatever, whereby the same effect may be produced; that is, I claim any means, in conjunction with an apparatus, which can, through the agency of the silk, retard or accelerate the receiving bobbin whereby silk can be conveyed from a swift, rise head, or reel, on which it is placed to be wound, to a bobbin which is to receive it, without any friction or tension being employed upon it, except that which is necessary for its action upon the said apparatus, and consequent self-preservation, and for laying it with a proper tightness on the bobbin, and which may be increased or diminished at will, by increasing or diminishing the action of the said apparatus on the bobbin itself.

"In fig. 3, I claim the arrangement there described generally, and particularly the channel of metal or other material F F, for supporting the skein in its passage from one rise head to the other. In fig. 6, 7, I claim the use of rods or bars of glass, or any other suitable substance, as heretofore described, by passing the silk under and over, by which a sufficient degree of tension is produced to lay it well upon the receiving bobbin, whereby the wire guiders commonly in use are rendered unnecessary, and much breakage and waste consequently prevented; if one or two of these rods or bars be covered with woollen cloth, or any other suitable substance, it would tend much to clean and brighten the silk, and to prevent loose ends running up. In fig. 6, 7, I also claim the particular arrangement, as described in the drawings, of the loops and wires a, a, a, which are made so peculiarly light and small as to produce but the slightest tension on silk, and yet sufficiently heavy to answer every purpose.

"In fig. 10, 11, I claim the general arrangement of the machinery, the particular arrangement of the cloth bars, waste preventers with the cutter, and the application of the same peculiar arrangement of parts to the common spinning mills, for the purpose of doubling and spinning at one operation.

"Lastly, I claim, whether for this or any other purpose, the exclusive application of the circular polished metal

rims, or other suitable substance, whose surface is not liable to be chipped or injured in ordinary use, termed 'waste preventers, as a substitute for the old fliers.'

"R. BADNELL."

For the subsequent operations in the silk manufacture, see the general article WEAVING.

Woollen and Worsted Manufactures.

(1015.) The history of the woollen manufacture, like most of the other useful Arts of ancient date, is involved in some obscurity. The Greeks give the honour of the invention of spinning and weaving wool to Minerva; it is, however, supposed to be of Asiatic origin, and is referred to by Moses in the Bible, as existing at least fifteen hundred years before the Christian Era.

In the early period of manufactures, whether in wool, cotton, or flax, the first steps were nearly the same; except so far as each being a different material, each required some peculiar preliminary preparation to fit it for the use of the actual manufacturer. We have seen in what manner cotton and flax are prepared for the spinner; in this article we have to describe the processes used with wool to reduce it to a like state. This, in the first attempts, was probably effected by the fingers, and afterwards by the application of some kind of comb, the use of which is of unknown date, and is continued in some processes to the present day. The invention of the wheel and spindle is also of unknown origin, but has obviously been practised for many Ages. In the infancy of this Art, and for many centuries after, the making of cloth was merely a domestic occupation; the fleece was gathered from the sheep, washed, opened, spun, and woven under the same roof which witnessed the preparation and the grinding of corn; consequently we may assume that little of perfection was either effected or aimed at; but in proportion as Society advanced and a division of labour became convenient, improvements were made, not only in the Arts of spinning and weaving, but in that of breeding and selecting those animals, whether sheep or goats, which gave the finest fleece. The produce of white wool from sheep is said to be entirely the result of cultivation, and is unknown in those Countries where it is not employed as an object of manufacture or commerce. We may imagine that, in the earliest state of the woollen manufacture, when cloth was simply a substitute for the skin of a beast as clothing, little attention was paid to the colour or fineness of the wool; but as luxuries were introduced coloured garments were required, and the wool could no longer be taken indifferently from sheep of all tints, from the white to the dark brown or black. The grower began then, therefore, to pay particular attention to the whiteness of his fleece, which was essential to the cloth, when made, receiving the brilliant dyes which, even in a very remote period, were certainly given to it.

With respect to the woollen manufactures of the Greeks and Romans, we have very scanty information, although it is obvious that the clothing of armies so large as they sent out must alone have required considerable manufactures; and although we have so little information as to the actual processes employed, or respecting the establishments in which they were conducted, yet there are various circumstances to prove that the latter People carried the manufacture of fine woollen cloth to a considerable degree of perfection, and paid particular attention to the breed of

Mechanical
Processes.

Early
history.

Woollen
manufac-
tures of the
Romans.

Manufac-
tures.

their sheep. Pliny describes two breeds of sheep, the one having long, coarse hair, which was on that account called *hirtum*, or *hirsutum*, and from its hardness and rougher treatment *colonium*; the other was called *molle*, from the softness of its wool, and *generosum* or noble, from its excellence, which latter was sold at a very high price. This breed had other distinguishing names, as Tarentinum, Apulum, Calabrum, Atticum, and Græcum, from the neighbourhood or district whence the fleece was derived. This breed was also called Asianum as the place of its origin, and is supposed to be the same as that we now call the Merino.

That the Romans imported their Tarentine sheep into their Western colonies, with the art of weaving fine cloth, is stated both by Strabo and Pliny. The former writer, who flourished in the time of Augustus, says, that in Turditanian, in Portugal, at that time a part of Spain, "they formerly imported many garments, but now their wool is better than that of the Corani, and so beautiful that a ram for the purpose of breeding was sold for a talent, (£216 sterling,) and that fabrics of extraordinary thinness were made of this wool by the Saltratae." The wool here alluded to is supposed to be that of Cashmere, of which shawls are manufactured in Persia. It appears that all classes of the Roman people wore woollen clothes, that of the lower Orders, no doubt, of an inferior description, but amongst the higher classes very fine cloth was used, and amongst these, probably, as a great object of luxury, was included cloth in imitation of the Indian shawl. When the Roman Empire, on its fall, was overrun by nations of Barbarians, whatever might have been the perfection at which it had arrived in the manufacture of the finer fabrics, the Art was entirely lost, and only that part saved from destruction which was connected with the making of the warmest and coarsest kinds of cloth.

Manufac-
tures in the
Low Coun-
tries.

In the middle of the Xth Century it seems to have revived a little in the Low Countries, in which it remained the source of great opulence to the people for more than four hundred years. In the first instance the wool which was used was the produce of their own pasture; but as the manufacture extended itself, the demand for wool became too great to be supplied by themselves, and was therefore derived from other Countries. The wealth which was thus acquired was seen by other nations, and people crowded into the Country, engaged in its commerce, and pushed their speculations with increasing vigour for another century and a half, when an inundation of the sea, which threatened the whole nation with ruin, caused a dispersion of the manufacturers, and spread the Art over a much larger space. This gave to the trade a new impetus, and was the means of establishing a connection between the Netherlands and foreign Countries, which ultimately proved of the highest importance to commerce. It contributed to a speedy recovery of the woollen manufacture from the ruin which seemed to threaten it, and gave a striking instance of the facility of re-establishing the Arts in any Country where they have once flourished under the patronage of a government liberal enough to encourage and sufficiently powerful to protect them even in situations attended with natural disadvantages. The influence of these manufactures upon the fleeces of the Low Countries must have been very considerable; for, before the year 960, there is no reason to suppose that their quality was

superior to those of the neighbouring districts, and yet Flanders and Brabant became famous for their cloths even before they imported much foreign wool. Mechanical Processes.

About the year 1200, the merchants began to import the wools of other Countries, to extend their connection much more widely, and they grew by this means much more rich and powerful. The ships of Spain and England carried their fleeces almost to the doors of the manufactories, and received in return little more than a supply of manufactured goods, which was probably not great, although it is said that the fleece formed full two-thirds of the value of the ewe that produced it, at least in England.

Soon after this time the woollen manufactures took root in many of the Countries of Europe. In Spain it had never, perhaps, been lost; and it is said that in 1218, not less than 16,000 looms were employed in the city of Seville alone. In 1353, the exportation of certain kinds of cloth was carried to such an extent in Spain, that it is said 935 bales of these goods were taken on board a Spanish vessel on its way to Alexandria, and 1000 bales on board another vessel in 1412; and in 1446, wool was sent from England to that Country to be manufactured into cloth, and returned. From Spain the manufacture travelled into Italy and France; and in 1646 Nicholas Cadeau, a Frenchman, had Letters Patent for twenty years, for making sedan, black and coloured cloths, like those of Holland, of the finest Spanish wool. Manufactures in Spain and France.

The inhabitants of the North of Europe were not at first able to manufacture fine Spanish wool without a mixture with that which was longer and coarser; but what in the beginning was a matter of great necessity, became afterwards an object of choice, and accordingly the more skilful clothiers, as well in Holland as elsewhere, either discarding the finer and dearer Spanish wool, or mixing it with the cheaper and coarser English, forming a warp of the latter which they covered with a woof of the former, contrived to make a cheap and serviceable cloth, which pleased the eye equally well with the more costly fabrics of entire Spanish wool. This, however, was carefully concealed at the time, but was afterwards candidly acknowledged by writers actually engaged in the commerce of wool, and sufficiently refuted the prejudices which had prevailed, from the middle of the XVIth Century to the middle of the XVIIth, that the wools of other Countries than that of Spain were inapplicable to the manufacture of very good and fine cloths.

In 1659, a Treaty was entered into by the Spanish and French Governments which enabled the latter freely to obtain the wool of the former, and thus to gain great advantage over the English in the Levant trade. From the proximity of the French to the woollen manufactures in the North of Spain, it might have been expected that the French would have engaged earlier in this manufacture; but owing to their frequent wars, and to their attention having been directed to the manufacture of silk, they do not appear to have commenced the fabrication of woollens for exportation extensively before the XVIth Century; but about this time France made great progress with her manufactures of wool, and in securing the export trade, particularly that of Tartary, for which she was better situated than England or Holland. The nature of her trade to warm climates directed her attention to the fabrication of the lighter and finer cloths; in consequence of which she preserved

Manufac-
tures.

the greater part of the Turkey trade even to the outbreak of the French Revolution, and at a much earlier date fine French cloths had attained a celebrity for their superiority of texture and dye over those of any other Country of Europe; and how long she might have retained the monopoly, founded on this preference, it is impossible to say, had not the Revocation of the Edict of Nantes driven many of her best hands, both in the woollen and worsted trade, to seek for shelter in other Countries, to which they carried the Art, hitherto almost exclusively French. In spite of this, however, although thenceforward may be dated the downfall of the French superiority, that Country supplied the greater part of her own population, then about twenty millions, with cloth, besides her foreign exports. Under Napoleon, the best Merino flocks were imported from Spain, and spread over the country very extensively, so that much fine wool has, since the Peace, been imported into England, as will be seen by the Tables we have given in a subsequent page. All has now, perhaps, been said that is requisite concerning the rise and progress of the woollen manufactures in Europe generally; we must now turn to Britain in particular, at present the great seat of manufactures of nearly every description, which, by means of her coals, machinery, and facilities of transport, she is able to bring with advantage into nearly every market of the world.

History of
the woollen
manufac-
tures of
England.

Woollen manufactures of England.—There appears some reason to suppose that the Romans, during their possession of England, established a manufacture of woollen cloths at Winchester; but the first distinct notice of a body of manufacturers occurs in the reign of Henry I., who are supposed to have been some of those driven out of Holland by the terrific inundation to which we have already referred. They are said to have been well received, and first placed in the neighbourhood of Carlisle, and towards Scotland, but were afterwards transferred to Pembrokeshire. This removal was made in the time of Henry I.; but mention is made of other cloth weavers in this reign both in London and Oxford. In the reign of Henry II. there were weavers at Nottingham, Huntingdon, York, Oxford, London, and Winchester, all of whom paid fines to the King for the privilege of carrying on their trades. There were also cloth dealers not only in the places above named, but in Norwich, Gloucester, Newcastle-upon-Tyne, Berkhamsted, Chesterfield, and in several towns in Lincolnshire, who also paid fines to the King for the privilege they possessed of buying, dyeing, and selling cloths. In the 31st of Henry II. the weavers of London received a confirmation of their guild with all the privileges they enjoyed under Henry I., and in their Patent it was directed, that if any weaver mixed Spanish wool with English in making cloth the magistrate should seize and burn it; this order was given under the pretence of the inferiority of the Spanish wool, but its real object was to encourage the growth of English wool, and to increase its quantity for the benefit of the King's revenue.

In the reign of Henry III. an Act was passed limiting the breadth of broad cloths, russets, &c. to two yards within the lists; and in 1284 another Act permitting foreign merchants to rent houses and to buy and sell their own commodities without any interruption from the citizens. In 1331, John Kemp, a master manufacturer from Flanders, received a protection to establish himself in England, with a number of dyers

and fullers, to carry on his trade; and in the following years several manufacturers came over from Brabant and Zealand. These were distributed over the country; at Norwich for the manufacture of woollen fustians, at Sudbury for baize, at Colchester for sayes and serges, in Kent for broad cloth, Devonshire kersies, Worcestershire, Yorkshire, &c., for cloth generally, and some other places.

In 1336, two woollen manufacturers from Brabant settled at York under the King's protection, who are supposed to have laid the foundation of the woollen and worsted manufactures which have since so extensively flourished in the Western part of that County. A few years after Thomas Blanket established a manufacture of coarse white cloth at Bristol, from whom the term blanket is supposed to be derived. In his first attempt he was so harassed by the Mayor and other members of that Corporation for fees, fines, and impositions, that he petitioned the King for Letters Patent to allow him the free exercise of his profession or trade without "impediment, calumny, or exaction."

At this time, 1357, the woollen trade of England was considerable, and the exports of some importance, as appears by the following Table of 28th of Edward III., said to be found in a record in the Exchequer, and published by Edward Misseldon, merchant, in 1623.

Exports and Imports of Woollen Cloths in 1355.

Export of
woollen
cloths in
1355.

<i>Exports.</i>		£.	s.	d.
Thirty-one thousand six hundred and fifty-one sacks and a half of wool, at £6 value each sack, amount to	189,909	0	0	
Three thousand thirty-six hundred and sixty-five felts, at 40s. value each hundred at six score, amount to	6,073	1	8	
Whereof the custom amounts to	81,624	1	1	
Fourteen last, seventeen dicker, and five hides of leather, after £6 value the last, amount to	89	5	0	
Whereof the custom amounts to	6	17	6	
Four thousand seven hundred and seventy-four cloths and a half of worsted, after £2 value the cloth, is	9,549	0	0	
Eight thousand and sixty-one pieces and a half of worsted, after 16s. 8d. value the piece, is...	6,717	18	4	
Whereof the custom amounts to	215	13	7	
Summary of the out-carried goods in value and custom	£294,184	17	2	

Imports.

One thousand eight hundred and thirty-two cloths, after £6 value the cloth, is	10,992	0	0
Whereof the custom amounts to	91	12	0

There is in the account from which this is taken no statement of wool imported; it would appear, therefore, that at this period the English manufactures employed only home-grown wool; and it will also be observed, that the cloth imported was more valuable than the exported, so that probably the former was made of the finer Spanish wools, and the latter of the coarser wools of the English flocks.

Many fraudulent practices having been had recourse to by English cloth manufacturers, an Act was passed in the reign of Richard II., which states, "Forasmuch as divers plain cloths, wrought in the Counties of Dorset, Somerset, Bristol, and Gloucester, be tacked and folded for sale, of which the greater part be broken, bruised, and not agreeing in colour, neither according to the breadth, and in no manner to the part of the same cloths

Mechanical
Processes.

Manufac-
tures.

showed outside, but falsely wrought with divers wools, to the great damage of the people, inasmuch that the merchants that buy the same, and carry them out of the realm to sell to strangers, be many times in danger of being slain, and sometimes imprisoned and put to fine and ransom, therefore it is ordained, that no plain cloth tacked and folded shall be set to sale within the same Counties." The same Act permits certain coarse cloth of wool to be made of the breadth of three-quarters, and appoints one weight and measure through the Kingdom, except in the County of Lancaster. Another Act allows cloth to be made of any breadth and length, provided "aulnage and other duties be paid on the same and no deceit be practised."

During this reign it appears that, notwithstanding the great extent of the woollen manufactures, the English annually exported about 130,000 packs of wool, paying a duty of £160,000.

Other Acts were passed in the reigns of Henry IV. and Henry VI. for regulating and enforcing various conditions on the manufacturer, amongst which was one in the latter reign appointing two cloth searchers to every County, whose duty was to inspect, search, and measure every piece, and to seal the same, for which duty they received one penny per piece. In this reign, also, the exportation of woollen yarn was prohibited, although that of wool was permitted.

Other regulations were introduced in the subsequent reigns, one of which, in that of Henry VII., fixed a maximum of price limiting the selling prices per yard for fine scarlet cloth to 16s., and that of other colours to 11s., imposing a fine of 40s. per yard for any one transgressing this Statute. In the reign of Henry VIII., both the woollen and worsted trade was very flourishing till this monarch entered into his wars with the Emperor Charles, which greatly affected the export trade to Spain and the Low Countries, so that the goods sent up to Blackwell-hall in London, which had been appointed in 1357 as a general cloth mart, found no purchasers. In 1551, one Company alone, privileged under the denomination of the merchants of the Stillyard, exported 44,000 pieces of cloths of all sorts, 60,000 white cloths, the former valued at £400,000, and the latter at £600,000, besides wools and woolfels. In the subsequent reigns of Edward VI., Mary, and in the beginning of that of Elizabeth, the woollen manufactures seem to have declined, principally, perhaps, in consequence of the injudicious regulations introduced from time to time granting privileges to one County or district and denying it to another. In one County wool might be bought and sold, in another it was prohibited; the fixing a maximum of price and various other vexatious enactments; but in the latter part of the reign of Elizabeth many of these oppressive Statutes were repealed. Hitherto the manufacturing of cloths had been confined to corporate towns, but the privilege was now extended to all persons resident in the Counties of Somerset, Gloucester, and Wilts; why other Counties had not the like privilege does not appear. This Act, however, served to extend the manufacture over a very large district, in which it has continued to flourish to the present time. Many other Acts were passed in this reign much at variance with our present ideas of freedom of trade, but wool was allowed to be exported. The internal tranquillity which the Country enjoyed during this long reign, the influx of foreign makers of new kinds of worsted goods and other articles, the opening new

foreign markets, viz., with Turkey and the Barbary States, all contributed to extend the woollen manufactures so much that the merchant adventurers alone, towards the commencement of the XVIIth Century, exported cloths and wool to the amount of one million sterling.

In the following reign new laws were made respecting the exportation of cloth; hitherto it was chiefly white cloths which had been exported, but this was now considered bad policy, as it was supposed that thereby the profit of the dyeing and dressing was lost to the nation. A letter exists, addressed to James I., in which it is stated, "that there have been eighty thousand undressed and undyed cloths exported yearly, by which the Kingdom has been deprived of £400,000 for the last fifty five years, which is nearly £20,000,000 that would have been gained by the labour of the workmen in that time, with the merchants' gains in bringing in dyeing wares, and return of cloth dressed and dyed, with other benefits to the realm." The writer, who has been supposed by some to have been Sir Walter Raleigh, states, that there had also been exported at that time annually 50,000 Devonshire white cloths, baizes, and kersies, whereby had been lost £5,000,000 to the nation in labour and profit. These baizes, the writer states, were dyed at Amsterdam and shipped to Spain, Portugal, and other Kingdoms, under the name of Flemish baize, setting their own seal upon them, "so that we lose the very name of our home-bred commodities." The writer then concludes by asserting, that the nation loses £1,000,000 a year by the exportation of white cloths. All this was according to the spirit of the Age, when interferences of all sorts were called for and adopted; but the impolicy of this measure was soon discovered, for no sooner was the prohibition granted to prevent the exportation of any but dyed cloths, than the Dutch and Germans prohibited the importation of any but white cloths, so that it was soon found that the nation lost instead of gained by the measure. In the subsequent reigns of the Stuarts religious persecutions tended greatly to depress the woollen trade. The descendants of the French Protestants who had before settled in Norfolk and Suffolk, for the sake of enjoying their Religion in peace, were now again attacked in their place of refuge, and many families of them were driven over to New England, while others went to Holland, where they were allowed to settle, with the privilege of being exempt from taxes for seven years, and thus their skill and knowledge were rendered available to our competitors in the woollen and worsted trades.

In 1668, a person named Brewer brought over about fifty workmen who wrought and dyed fine woollen cloths, in the manufacture of which the English had hitherto been very deficient. This party received the protection of Charles II., and from them the English were first instructed how to manufacture cloth of the best Spanish wool, and also to dye their fine cloth at about forty per cent. less expense than they had formerly been able to do. Notwithstanding, however, this circumstance, it appears that the cloth trade declined during this reign, and that on a representation being made to the merchant adventurers for their neglect of it, they stated that the demand for English cloths failed in the foreign market, and that the white clothing had abated from 100,000 pieces annually to 11,000.

It was not till the reign of William III. that the manufactures of woollen cloths became firmly fixed and

Mechanical
Processes.

Manufactures. progressive in the Country, as will be seen by the returns of the exports. In the year of the Revolution the export of woollens alone was nearly £3,000,000, at which it remained pretty steady till 1715.

In 1718 the value of woollens exported was	£. 2,673,696
1719.....ditto.....	2,730,297
1720.....ditto.....	3,059,049
1721.....ditto.....	2,903,310
1722.....ditto.....	3,384,842
From 1739 to 1748 medium annual value..	3,327,059

In 1816.....ditto.....	8,404,481

In the subsequent Tables will be seen the amount of Exportation from 1820 to 1831, the importation and other particulars, which will give a tolerable view of the state of the woollen manufactures since the introduction of the most recent improvements in machinery.

We have not in the preceding historical sketch made any particular distinction between the woollen and the worsted manufactures; the latter is supposed to have been introduced into this Country about the year 1336, and within a few years after that period had attained a considerable degree of importance, but in subsequent periods it was subject, like the woollen trade generally, to various fluctuations. Its exports and imports are included in the following Tables.

An Account of the Quantity of Foreign Wool imported into, and of Foreign and British Wool and Woollen Yarn exported from the United Kingdom, in each Year, from 1820 to 1831, both inclusive.

Years.	Foreign Wool Imported.	Foreign Wool Exported.	British Wool Exported.	Woollen Yarn Exported.
	lbs.	lbs.	lbs.	lbs.
1820	9,775,605	64,585	35,242	3,924
1821	16,622,567	291,318	34,226	9,121
1822	19,058,080	233,872	33,208	12,515
1823	19,366,725	200,776	28,563	6,423
1824	22,564,485	419,594	53,743	12,640
1825	43,816,966	678,034	112,424	76,961
1826	15,989,112	888,651	143,130	131,032

1828	30,236,059	872,249	1,669,389	436,722
1829	21,516,649	406,566	1,332,097	589,558
1830	32,305,314	659,242	2,951,100	1,108,023
1831	31,625,029	1,025,962	3,494,275	1,592,455

Mechanical Processes. The above Table gives the total of the importation and exportation for the several years therein stated, and in the following three Tables will be found the particular importation and exportation, and the names of the Countries from or to which it is made. We have selected three years at nearly equal periods in order to show the progressive increase or decrease of our trade with these several Countries and Colonies.

A Return of the Quantity of Foreign Wool imported, and of British Wool and Yarn exported, with the Countries from or to which it was made, in the Years 1820, 1825, and 1832.

Processes
of the
manufac-
ture.

(1016.) *Processes in the woollen manufacture.*—In sketching the rise and progress of the woollen manufactures of this Country, our remarks have generally been made with reference to the impediments and encouragements which they have sustained and received from different Kings and Governors, their localities, &c., and nothing has been said with respect to alterations and improvements in the manipulations and mechanical means by which they were conducted. Indeed, from the earliest period of those manufactures to the latter end of the last century, very few, if any, mechanical improvements had taken place; the only change, where any took place, being in the increased skill and dexterity of the operator, and in a choice of materials better suited for particular purposes. The carding and spinning wool for cloth, and the combing, spinning, &c. for worsted yarn, as also the processes for dyeing and dressing of cloth, in the early part of the reign of George III., were effected by the same means as in the time of Edward III., which probably were similar to those of the ancient Romans, except that perhaps the earlier machines were somewhat more rude in their construction. In an Art which had for so many centuries rolled on without any change, it did not appear possible to the manufacturer that any improvement could be effected; and had not the genius of Hargreaves and Arkwright changed entirely the modes of carding and spinning cotton, the woollen manufacture would probably have remained at this day what it was in the earliest stages of civilized Society. Some writers, amongst whom we may men-

tion the author of the article *Woollen Manufactures*, in Rees's *Cyclopædia*, to whom we are indebted for several particulars, are of opinion that it would have been better for mankind had they so remained, a doctrine, however, to which we cannot subscribe. At all events, it was impossible, after the invention of the spinning jenny, and the water frame or roller spinning, that the woollen yarn should still be a mere hand operation on a single thread at a time.

The spinning jenny for woollen yarn, which was precisely similar, but somewhat larger, than that employed in the cotton manufacture, was first introduced into Yorkshire in 1780, but did not become general till about three years afterwards. In the first jennies not more than eighteen or twenty threads could be spun, and the mode of winding the thread upon the spindle was very imperfect. The carding was still effected by hand, and the slubbing or roving was prepared on the common spinning wheel. For some time considerable difficulty was experienced in the carding machinery, particularly in clearing the wool from the card, and a slight change in the form of the machine was found necessary to prepare the wool for the slubbing billy. Soon after this, the carding and spinning woollen yarn became general through the manufacturing district of the West Riding of Yorkshire; a large mill was erected in which the carding and scribbling machines were turned by water wheels, and the roving or slubbing performed on the billy. The wool carded at these mills was sent to the smaller manufacturers in the state of slubbing, and the

Manufac-
tures.

further process of spinning was conducted by these persons with jennies on their own premises. Before the year 1790, the old processes of carding by hand and spinning on the wheel were entirely discontinued in Yorkshire; but it was some years after before the new processes were generally introduced into the West of England. Soon after this period the steam-engine, which had then only recently been employed for propelling machinery, was introduced into Yorkshire for the purposes to which the water wheel had been applied, and it is now commonly used in the principal woollen manufactories. We now proceed to describe the several processes.

Wool mill
or devil.

(1017.) *Wool mill, called also a devil.*—This is differently constructed in different manufactories, but the most common form consists of a cylindrical drum, about three feet long and two and a half feet in diameter, furnished with teeth or spikes throughout its surface or circumference; this turns on an axis fixed in a strong wooden frame enclosed on all sides, but the ends of the case turning on hinges which allow them to be let down; the lower part is not, however, close boarded, but splinted, so as to admit any dirt, extracted by the operation, to fall through. On the axle of this drum is a wheel, and over the cylinder within the case are five smaller rollers or cylinders, also covered with teeth, and turning on axes fixed in the frame. The teeth of the rollers and those of the drum or cylinder intersect each other during the rotation, as do also the teeth of the rollers themselves; motion is given to the whole by a fast and loose pulley, or other contrivance, to connect the machine with the first mover. The front door is now turned down on its hinges, and a quantity of raw wool, as it is received from the wool stapler, is laid upon it; the door is then closed, by which means the wool is brought within reach of the teeth of the drum or central cylinder, which carries it upwards so as to work it between its own teeth and those of the upper rollers. The motion of the cylinder is very rapid, and as the wool is drawn from tooth to tooth, it is opened and the longer fibres broken; after a certain number of revolutions, a door, similar to the one last described, is opened at the other end of the machine, and the wool is thrown out by the centrifugal force of the cylinder; it is then again closed, the former one opened and supplied with another charge of wool, which is in like manner ejected, and so on with fresh charges, each being about a pound in weight.

This operation is sometimes repeated several times; when the dye is given to the wool, it is repeated after dyeing; it is employed also for mixing different wools together.

Scribbling
machine.

(1018.) *Scribbling machine.*—This machine resembles in some measure that last described, consisting of one large central cylinder with smaller ones in pairs, called workers and clearers, which, however, are covered on their surfaces with cards instead of the strong teeth, and the wool is supplied by a feeding apparatus, after the manner explained under carding, in the cotton manufacture. The centre cylinder is turned rapidly by means of its connection with the first mover, and the wool is scribbled or carded in its passage between the teeth of the cards on the cylinder and rollers, which do not, however, in this machine, intersect each other, but are brought so near that the fibres of the wool which the teeth of one card contains are caught by the teeth of the other card, and drawn out a few at a time. This separates the fibres and makes

the wool light and open, and also distributes it with great evenness over the surface of the cylinders. After it has passed between three or four pairs of workers and clearers, (the former being the denomination of the small rollers which take the wool from the great cylinder, and the latter that which take it from the worker,) it is taken up by another cylinder called the doffer, from which it is stripped off by a comb, precisely as we have described in the carding machine in the cotton manufacture, (Art. 990.) except that it falls in a continuous fleece instead of being condensed into the form of a roving. This operation is repeated two or three times, till it is at length reduced to a proper state for carding. In several manufactories, however, a double scribbling machine is employed, when sometimes one operation suffices, but it is commonly afterwards passed through a single machine; in this double machine the second great cylinder receives its wool from the doffer of the former, and one comb only is therefore necessary.

(1019.) *Carding machine.*—This is framed on nearly the same principle as the scribbling machine, except that the doffer is not entirely covered with teeth, but with strips of cards about four inches in breadth, and which are therefore stripped off from the doffer in very delicate films or webs of that breadth, and about twenty-seven or twenty-eight inches in length, i. e. of the length of the doffer. These are rendered cylindrical by falling into a concave semi-cylindrical shell or case, in which a fluted cylinder revolves, and which gives to these films of wool a cylindrical figure, which is the first element of the thread; when they arrive at the further side of the above cylindrical shell, they fall out in their condensed form upon an endless cloth stretched over two rollers or cylinders; this is continually revolving, and as each sliver arrives at the edge of the cloth it is removed to the next machine, which is called in the cloth manufacture a slubbing billy, differing only in degree from the roving billy in the cotton manufacture; the several slivers are laid in succession on a feeding cloth, and their ends slightly combined by boys or girls employed for the purpose.

(1020.) In the *slubbing billy*, the thread first becomes continuous, and is in this state called, in cloth-works, billy. a slubbing, corresponding to what is denominated a roving in the cotton; and all its subsequent processes differ so little from those which have been described in cotton roving, spinning, &c., as to render it quite unnecessary to enter into particulars. It will easily be imagined that two textures differing so much as wool and cotton require some differences in the proportions of the different parts of the machines, and in the degree of speed with which the machinery is driven; but these are minutiae which would scarcely be distinguished were we to give separate drawings of the machines, we refer, therefore, to roving and spinning in the article COTTON MANUFACTURE. The next steps of course, after the thread or yarn has been properly formed, is that of warping and weaving, which we propose to describe generally for various goods under the article WEAVING. We shall, therefore, now consider the material as manufactured into cloth, and endeavour to illustrate the subsequent operations which it has then to undergo before it is considered in a fit state for the general market.

(1021.) *Processes subsequent to weaving.*—It is essential to the manufacture of cloth that a certain quantity of Fulling, &c. milling, &c.

Manufac-
tures.

oil should be employed, and therefore the piece as received from the hands of the weaver is not in a state for immediate use; it is greasy and rough, and has to undergo several operations before it acquires that smooth and level surface which is at length given even to cloths of very common quality. The first step to be taken is that of scouring; this is effected by first soaking the cloth for some hours in alkaline mixtures, and afterwards in clear water; this neutralizes the grease and allows of its more easy removal. In this state it is taken to the fulling mill, and worked with the heads of the stocks, as described under FULLING MILL. (Art. 501.) This process being completed, it is taken to the *tenter field* and stretched on tenter frames. These consist of a number of vertical posts fixed in the ground, with a continuous horizontal fixed rail at top as long as the piece of cloth; there are also other horizontal rails which are fitted between the upright posts, so as to slide freely up and down, and can be fixed at any distance beneath the upper rails by means of holes and pins, according to the width of the piece of cloth; both the upper and lower rails are driven full of tenterhooks; on these the lists of the cloth are fastened, after which the lower or movable rail is pressed downwards to the full breadth of the cloth, and then secured in its place by the pins above mentioned. In this state the pieces are left to dry; they are then removed and minutely examined in every part, and all knots and uneven parts removed, and any rents or defects which can be found are repaired by introducing fresh threads with a needle; this operation is, in the language of the manufacturer, called *burling*.

Milling
and felting.

The next process is that of *milling* or *felting* the cloth. In the state in which cloth is received from the tenter field the naked threads are very perceptible, and the subsequent operation of milling is to swell the threads, and felt them so as to allow of the cloth afterwards receiving that fine, smooth, and polished surface which is the great beauty of fine cloth, and which renders it also more impervious to wet. Commonly, a piece of cloth of sixty-two yards requires six pounds of soap, which is dissolved in water, and about a handful spread upon each yard in length; the piece is then put into a trough and worked for three hours in the fulling mill, during which the cloth is frequently moved as described. (Art. 502.) The blows upon the cloth cause a motion of the fibres of the wool amongst each other which is facilitated by the soap; by this means the mixing, entangling, and matting of the fibres is produced, constituting the felting.

After the three hours' milling, the cloth is taken out of the trough and again soaped, and is then returned for three hours more. This is repeated four times, making twelve hours' milling in the whole, and then a stream of clear water is admitted into the trough to wash away the soap. The piece of cloth is commonly, at the conclusion of this operation, reduced in breadth about two-fifths, and in length one-third. It is now again stretched on the tenter frame, in which it is extended in length about one-twentieth, or two yards in forty; but it is not stretched in breadth, or very little. The cloth remains in the open air till it is quite dry and ready for the final operations of dressing and shearing.

Dressing.

(1022.) *Dressing*.—In this process the nap of the cloth is raised, by the action of what are called *teasles*, a species of thistles, to its surface. These are cultivated in different parts of England, and supplied to our clothiers

for the purpose; they are hard balls covered with scales terminating in strong stiff points, which turn downward like hooks and are very elastic. Formerly a number of these were arranged in frames so as to form a kind of hand card; and the dressing was performed by two men who held the teasle frame by its handle, and worked the cloth with it, the cloth itself having been hung up in a vertical position; when one part was finished another part was brought forward, and so on till the work was completed; and this was repeated three times, the cloth being wetted, and then three times after being dried. This hand process, however, is now almost or entirely discontinued, and the dressing is effected by machinery, and in some cases fine wire cards are made to supply the place of the teasles; this machine is denominated a *gig mill*.

(1023.) The *gig mill*, like most other machinery connected with manufactures generally, and that of cloth in particular, varies considerably in form in different manufactories. In that represented in plate lxxii. fig. 1, *Pl. lxxii. Fig. 1.* F F, &c. are frames of teasles ranged round a large central frame constituting a sort of drum, which receives its motion from a strap over the pulley D, which, by the wheelwork shown in the figure, gives motion to the drum and to the upper and lower rollers. The piece of cloth is wound tightly and smoothly upon the lower beam, as it passes thence to the upper beam; jets of water are also supplied from the horizontal pipe N, to give a proper degree of moisture. The machine being now put in motion, the working of the surface of the cloth is effected by the rotation of the teasle drum; and the upper beam, whose motion is properly regulated by the wheel gear, is made to receive the cloth at precisely the speed with which it is delivered from below. The first operation being completed, the rollers are made to change place, and the operation is then repeated as often as requisite.

(1024.) *Shearing*.—The nap having been sufficiently raised by the foregoing operation, we arrive at the final process of shearing. It will be obvious that the wool raised by the teasles will cover the surface of the cloth after the manner of a loose fur, which must now be removed by proper means; this is called shearing or cropping.

This was formerly, and is at this time, frequently performed by hand. The clothier's shears consists of two very large blades of steel united together by a steel stem which is bent into a bow, but is sufficiently flexible to allow one of the blades to be moved upon the other in order to make them cut; both blades are ground to sharp and straight edges, which apply one to the other, but they are not in parallel planes like those of a pair of scissors, but inclined at an angle of about forty-five degrees; that is, one of the blades being laid flat upon the cloth, the other will then be inclined to the cloth at the above angle. The cutting edge of this inclined blade bears upon the surface of the flat blade, and the spring of the blade is so set as to press the two edges always together. The lines of the edges of the two blades are not parallel to each other, but so inclined that the edge of the upper blade crosses the edge of the lower, and bears upon its flat surface at the end nearest to the bow, whilst the other end of the edge of the upper blade is removed over the edge of the lower, thus leaving an interval between the two edges when the shears are open. In this state, the shears being opened, if the lower blade be laid flat upon the surface of the cloth, the nap or wool which is to be removed by

Shearing
by hand.

Manufac-
tures.

the cropping will stand up above the edge of the lower blade, in the interval between the two edges, then, if the blades be forced together, the edge of the upper blade will pass or cross over that of the lower, and cut away all the wool which projects above the edge of the lower blade. The contact of the cutting edges begins at the end nearest to the bow and proceeds regularly to the other, in consequence of the two edges not being parallel as above explained. The blades open or return to their former position by the elasticity of the bow, and in order to make the cut they are closed by means of a handle or lever, which is fitted or lodged on a round part of the stem of the bow, so as to play thereon as upon a centre of motion. A double cord is made fast to this lever or handle near to the centre, the other end of the cord is fastened to a block of wood which is screwed to the flat of the lower blade, and rises up to a proper height; by depressing this handle the shears are closed, and make their cut with the greatest facility, when, as already described, the elasticity of the bow returns the blade and handle to their original position.

The operation is as follows. The piece of cloth is laid down in folds upon a plank or low bench placed on the ground, and the end is drawn across a table or bench which is covered with cloth and stuffed with horse hair, forming a large flat cushion. The cloth is stretched out flat upon the surface of the table, and is retained by hooks and weights. Two workmen are employed to shear a piece of cloth; they place the lower blades of their shears flat on the surface of the cloth, with the line of the edge in the direction of the length of the piece; one of the shears is laid on the edge or list of the cloth, and the other exactly in the middle of the breadth of the cloth. The bows and stems of the shears project over the edge of the table, and the workmen place themselves at that edge; each man guides the shears with his left hand, and makes the cut with his right; a short staff is lashed to the bow of the shears to hold them by, and secured by a stay to the lower blade; its direction is nearly parallel to the back edge of the upper blade. The workman puts his arm through the bow as far as the elbow joint, then lays the fore arm flat against the staff, which he grasps with the hand; and in this way he has a great command of the shears, leaving the right hand at liberty to work the handle which closes the shears. This handle is moved backwards and forwards with great rapidity, to make cuts or clips on the cloth, and between every cut the lower blade is moved a small space on the cloth to cut in a fresh part.

The art of shearing consists in moving the shears with great regularity and parallelism, so that every part of the surface shall be equally cropped. The closeness with which the shears cut is regulated by weights laid upon the flat of the lower blade; these press the blade down into the soft cushion on which the cloth is spread, so that the fur will stand up more above the edge of the blade.

(1025.) *Shearing or cropping machines* have now very commonly superseded the hand shearing, but they are so variable in their construction and action, that it is impossible to give any minute description. The first attempt was that of the shearing frame, which was merely a contrivance to work similar shears to those we have described by machinery instead of the hands of the workman. At the side of the table or cushion on which the cloth is spread a long stool is placed having

grooves at the edges to guide the wheels of a carriage on which the shears are fixed by their bows. There is a carriage for each pair of shears, and they are smoothly and slowly moved along the stool by a cord which winds upon a roller turned by wheelwork, and at the same time the handles of the shears are continually pulled by a cord connected with a small crank which turns very rapidly; the direction of the cut is lengthwise of the piece of cloth, and the two pairs of shears advance across the breadth until the whole is cut; the machine is then stopped, the shears removed, and the piece of cloth shifted upon the table, and a similar process repeated, and so on. This method is still practised in many manufactories, but the perpetually shearing or cropping engines are generally superseding all other methods. Of these we have still many varieties, but we must confine our description to one only; and we select that of Mr. Price, of Stroud, in Gloucestershire, which is explained at large in vol. xxix. of the *Repertory of Arts*. This machine shears or crops the cloth across the breadth, beginning at one end of the piece and continuing regularly to the other. For this purpose the cloth is conducted through the machine by the motion of rollers, and is drawn over a bed or support which lies beneath the fixed blade of the shears, (which answers to what is called the ledger blade in the common shears,) so that the cloth passes between the bed and the stationary blade.

The moving blades of the shears are fixed on the circumference of a cylinder situated above the fixed blade, with its axis exactly parallel thereto, and capable of revolving by the power of machinery, so that the edges of the moving blades will be carried against and passed over the edge of the fixed blade, in order to cut away all the wool of the cloth which rises above the edge of the fixed blade. Several such moving blades are fixed upon the same cylinder to act in succession against the fixed blade, and these moving blades are placed obliquely to the axis of the cylinder, or in such a manner as to form portions of spirals; but as all parts of the cutting edges are equidistant from the axis of the cylinder, it is manifest that, in the revolution of the cylinder, every part of each spiral edge is brought in succession into contact with the fixed blade, so that in its revolution it crops off all the wool which, by the progressive motion of the cloth over its bed, is raised up against the fixed edge. The edges of the moving blades are placed at such a degree of obliquity to the axis of the cylinder, that, at the same instant the end of one ceases to cut against the edge of the fixed blade, the following revolving blade will begin its action at the other end of the cylinder; therefore, by the time that any one of the revolving edges has passed over and made its cut against the whole length of the fixed blade, and is ready to quit it, the succeeding revolving edge is brought into action, and when this has passed, the next in succession begins, so as to keep up a continued action.

The cloth is stretched in width by a contrivance which Mr. Price calls stretching bands, to prevent it getting into folds or wrinkles, which would be injured by the shears, or make irregularities in the shearing. These stretching bands are endless straps or bands, each of which is extended over two wheels. The bands have sharp pins projecting from them into the lists at the edges of the cloth, and being so situated that one of them lies exactly beneath each list, they are

Mechanical
Processes.

Shearing
by ma-
chinery.

Manufac-
tures.

caused to circulate round their respective wheels by the motion of the cloth. The stretching of the cloth is effected by the position of the wheels on which the bands circulate, the direction of the bands being slightly oblique to the lengthways of the cloth. The endless straps are so fitted into grooves or troughs, that they are firmly retained to move straight forwards in their oblique direction; and the direction of the obliquity is such, that the bands are nearest together at that end where their pins take hold of the lists of the cloth; but as the bands move forwards with the cloth they recede from each other, and extend the cloth in breadth in consequence of their obliquity, which may be decreased or diminished as is found necessary. The actual width between the two bands is also to be regulated according to the width of the piece of cloth. It is not usual to crop the lists of the cloth; and, indeed, as the lists are usually of thicker substance than the other part of the cloth, they would bear up the fixed blade too high from the cloth to cut the nap quite close; for this reason, the bed or support on which the cloth is cut is so constructed that it can be adapted in length to the breadth of the piece of cloth between the lists, in order that the cloth only may be supported or borne up to the edge of the fixed blade, whilst the lists, being depressed or borne down below the level of the bed, (by thin slips of metal called guards,) will escape the action of cropping, and thereby remain with the long wool upon their surfaces. The bed by which the cloth is borne whilst it is cut is only a narrow ridge of metal, over which it passes so as to be bent with a sudden curvature, and in this way the nap can be cut more close and even than upon a flat bed or soft cushion. The operation of cutting is facilitated by a row of pieces of metal screwed to a strong bar to form a straight edge, very similar to the cutting edge of the fixed blade, but thin and elastic; this edge is placed close to the elevated ridge of the bed, and presses the cloth gently down upon the bed immediately before it comes to the edge of the fixed blade, against which the nap is to be cut off; this elastic edge being placed on one side of the ridge, and the cutting edge of the lower blade on the other side, the cloth is only exposed for a very narrow space just where it comes to the cutting edge. By this means the cloth can with safety be brought nearer to a level with the upper surface of the fixed blade, so as to shear it closer than could otherwise be done without endangering the cloth.

The ends of the ridge part of the bed are composed of a number of narrow plates of metal accurately fitted together, and placed side by side in a mortise made in the end of the solid bed; their upper ends project out from the mortise so as to line with the elevated ridge and form a continuation thereof, but there is a sliding piece in the bottom of the mortise on which they all bear, and the point of it is of a wedge form. By removing this wedge, any number of the movable pieces may be let down, so as to diminish the length of the elevated part of the bed at pleasure, according to the breadth of the cloth. The whole of this machine is very well contrived to effect the desired object: it will be found fully described, with drawings, in the *Repertory of Arts*, vol. xxix.; see also vol. xviii., lviii., lx., and many others, on the subjects of dressing, cropping, &c. The goods in this state require only to be brushed, pressed, and packed to fit them for the general market.

Worsted
manufac-
ture.

(1026.) *Worsted manufacture*.—We have said all that is necessary relative to the history of the worsted manu-

facture, in our general sketch of that of the woollen Mechanical Processes. manufacture, of which, indeed, the worsted is only a particular, although a very extensive, branch, the original material in both cases being the same. The principal difference is that, in what is commonly called woollen cloths, a nap or pile is raised so as to hide the threads of which it is composed, whereas in worsted stuffs, there being no pile, the threads are exposed. In the former, also, the shorter wool is employed and the longer fibres broken down by the wool mill and carding machine, whereas in this, long wools are preferred and the shorter fibres rejected. Moreover, the yarn is doubled and twisted much harder, and what little floss or woolliness may appear on its surface is frequently removed by singeing. The first operation in the worsted manufacture is that of combing, which was formerly wholly performed by hand, and is so still to a considerable extent, although some successful attempts have been recently made to effect this by machinery.

(1027.) *Wool-combing by hand*.—The wool being first washed in soap and water to cleanse it from the dirt and other impurities, it is drained from all superfluous moisture and thrown lightly into a basket. It is then separated by the comber into handfulls of about four ounces each, which he sprinkles with oil and rolls in his hands to distribute the oil uniformly.

This he transfers to his comb, which is a sort of hackle, resembling in some measure the hackle represented in flax manufacture. A pair of combs is represented in pl. lxxii. fig. 2; each is composed of two rows of teeth of well-tempered pointed steel disposed in two parallel planes, one row being longer than the other. These are fixed to a wooden stock or head which is covered with horn, and to this head is attached a wooden handle. Each workman has two of these combs, and as it is essential to this process that the teeth should have a certain heat to produce the best effect, it is necessary also that he should be provided with a comb pot, commonly containing a charcoal fire for heating the teeth. The comb pot generally contains eight openings for inserting the combs, so that one is sufficient for four workmen. See fig. 3. The only other essential part is a post or pillar, fig. 4, to which either comb may be attached for drawing the sliver.

The teeth of the comb being heated, it is fixed to the pillar above mentioned, with its teeth uppermost, and is then filled with wool. The workman, taking about half a handfull, catches it upon the teeth of the fixed comb, and by drawing the wool towards him, and at the same time downwards, a portion of the wool is left; and this is repeated till all the wool is gathered upon the teeth. The comb thus filled is placed with its teeth in the stove or pot, the wool being outside, the other comb is then filled in the same way and placed in the pot to be heated. Both combs being thus filled and heated, the comber holds one of them in his left hand over his knee as he is seated on a low stool, and with the other comb in his right hand he combs the wool upon the first by introducing the points of the teeth of one comb into the wool contained in the other, and drawing them through it until the fibres of the wool are disentangled and laid parallel. During the working, he frequently changes the combs hand for hand; but as the wool will accumulate upon that comb which is most worked, he manages so that, at the end of about five and thirty or forty strokes, nearly all the wool will be gathered upon one of the combs and hang down

Manufactures.

from its teeth in a fair lock of straight and regular wool. This comb is then put to heat for a short time; he then fixes it to the post and proceeds to draw the wool from the comb in a sliver. This is done by his taking hold of the projecting wool with the fingers and thumbs of both hands, and drawing it away from the teeth in a direction perpendicular to their plane without sliding it off their points, and as the wool comes away seizing it again near the teeth, and so on. This being done, a portion of short wool will not come off, as he never seizes hold but at a certain distance from the teeth; this, therefore, remaining after the sliver is drawn is removed; it is unfit for worsted spinning, and is therefore collected under the name of noil, to be applied for other purposes. The wool thus drawn from the comb forms a long sliver, the fibres of which are straight and parallel, but not sufficiently so for spinning, the process is therefore repeated a second and sometimes a third time.

Wool-combing by machinery.

(1028.) *Combing by machinery.*—The first attempt of this kind was made by Mr. Cartwright, in 1790; but since that time there have been many, the greater number of which, however, were failures, either from a want of perfection or a want of encouragement; of these we may mention Wright and Hawksley's Patent in 1793, and another of the same date by Mr. Toplis. In 1797, another Patent was taken out by Hawksley. Mr. Arnatt and Mr. Pearce also took out Patents for wool-combing by machinery, the former in 1795, and the latter in 1798; since which time Mr. Gilpin and several others have produced machines for this purpose, some of which are now employed, and a considerable quantity of wool is at this day combed by machinery. Mr. Gilpin's machine consists of two wheels, each carrying four combs at equal distances, so placed that, as the wheels pass each other in their rotation in opposite directions, the teeth of the opposite combs meet each other. The combs are so made that they can be readily removed from the wheels or frames, and be as readily replaced, and can therefore be heated the same as hand combs; the wool is also filled upon the combs by hand, and the combs and wool heated in the usual manner before they are put into the machine.

Mr. Gilpin's machine.

One of these comb frames is simply turned upon its axis by the first mover of the mill; but the other has a compound motion given to it by means of machinery, so that while it revolves on its own axis, this axis advances and recedes from the other frame with a motion parallel to itself, which is repeated four times every revolution. The advancing motion is gradual and limited to a certain extent, but at the same time there is a third movement which regulates this extent, so that every succeeding stroke the two frames will approach nearer to each other, and the returning or receding motion is made with three times the speed of the advancing or forward motion. This is effected by the circular motion of the frames being driven by an elliptical wheel, which occasions them to move alternately quicker and slower, according as the second wheel is advancing or drawing. In this way they continue to make successive strokes till the wool is sufficiently combed, the machine is then stopped, and the combs taken off one by one, to be replaced by others, which are filled with fresh wool and properly heated. There is, however, another motion in the wheel, which we have described as turning on a fixed axis, which has not yet been mentioned; the axis of that wheel has a slow

Mechanical Processes.

motion backwards and forwards endwise, in the direction of its length, for a short distance. The intention of this is that the same parts of the combs shall never come opposite to each other at two successive strokes.

It should be observed that, when the machine is first set to work, the combs at their point of meeting do not come within three or four inches of each other, and the points only penetrate amongst the longest fibres of the wool upon the combs; but at every stroke which is made, the combs advance nearer together, and take deeper into the wool, until after a certain number of strokes are made the combs approach as near as they can without touching. They continue to work in this manner for some time, and when the intended number of strokes is made a bell rings, as an indication that the machine should be stopped. This is done by drawing a lever, and in consequence the machine will stop itself in the exact position for changing one of the combs on each frame. These are removed, and others, ready filled with wool and heated, are put on in their places, which, being done on both frames at the same time by two persons, is only the work of a moment. The machine is then put in motion, but by the machinery it will stop itself again at the required position for changing the next pair of combs; it is then put forwards, and so on, until all the eight combs are changed.

The combs which are removed from the machine are put into the stove to heat for a few moments, and then the wool is drawn off from them by a separate machine. The head of the frame or reel is here placed in a perpendicular groove, so that its teeth stand horizontal; and a piece of metal, which is fixed to the head of the comb, and projects therefrom like a tooth, enters into the spiral groove of a screw, which stands in a perpendicular position, and is continually turned round by the machinery. By this means the comb is regularly and slowly let down in the groove from top to bottom. A pair of fluted rollers is placed horizontally and parallel to the teeth of the comb, in such a position that the comb, in descending, will pass with its teeth at a proper distance from them, to draw off the wool in a sliver; after passing through these fluted rollers, the sliver is conducted through a perpendicular revolving tube, which gives a roundness to it, the same as it would acquire by being rolled between the hands, and then it is conducted between a pair of plain rollers, which deliver it into a tin can placed before the machine.

A wooden roller is placed above the fluted rollers, with eight pieces of board projecting from it in the direction of radii; when the roller turns round, these boards act to stroke the wool upon the comb and raise it into a proper situation to be drawn off by the fluted rollers. The combs are prepared for drawing off the wool by heating them, as before mentioned, and by sliding the wool from the roots of the teeth halfway towards their points; in this state the combs are carried one by one to the drawing-off machine, and the head of one comb is put into the top of the perpendicular groove by the projecting tooth, which enters the spiral groove of the perpendicular screw. The wool is now gathered up and introduced between the fluted rollers, the machine is put in motion, and by means of the screw the comb is gradually lower down, and the wool is drawn off from it in a sliver, which is rolled up into a compact form by the revolving tube, through which it passes, and is delivered into the can by the plain

Manufac-
tures.

rollers; the attendant holds another comb ready to follow the first, and when it has descended to a certain point, he slips the next comb into the perpendicular groove, so that it rests upon the former, and the wool upon the two combs joins as it were in one. The stroker, when they pass before it, lays the fibres all one way, and the wool is drawn off by the rollers in a continued sliver, which does not present the slightest appearance of joinings; another comb is then put in, and the wool joins to the former, and so on. The backings, or wool at the back of the combs, are drawn off by the boy stationed at the back of the machine; and the combs, as they come through below, are received by boys, who afterwards take away the noil or short wool which remains in the teeth, and then put the combs back into the stove to heat them, ready to be filled again, in order to proceed with another combing. When the wool of all the eight combs is drawn off, the motion of the drawing-off machine is stopped at the moment when the eighth or last comb has descended half way through its course. In this state the machine waits till another combing is finished, and then the succeeding comb being placed on the top of that one which continues in the machine, the continuity of the sliver will be preserved.

The inventor of this machine states in his specification, that for common work the wool only requires to be operated upon once by the combing machine; and in that case, the machine must be adapted to make twenty-four strokes of eight pair of combs before the bell rings. For medium work, such as would require to be combed twice over in the usual manner of hand-combing, it must be combed twice over by the machine; thus, after having been combed once in the manner described, the sliver of wool is broken up into handfulls, and filled on the combs again by hand as before, and combed over again in a similar manner, but the combs are less heated for the second time of combing. By changing a wheel, the machine may be adapted to make only fourteen or sixteen strokes before it stops, when it is intended to comb twice over. The wool intended for the finest spinning should be combed three times over, and the machine should be set to make fourteen or sixteen strokes for each pair of combs. The machine has also two different movements for the drawing out of the movable comb reel; in one, the motion is over a space of ten inches, and is adapted to comb wool having six or eight inches length of staple, and is called wether wool; but by a slight alteration, the excursion of the movable reel can be increased to thirteen inches, and is then adapted to comb wool which has from eight to eleven inches length of staple.

Mr. Gilpin's machine has the advantage of heating the combs and of filling them by hand, both of which are essential to any machine which is proposed to comb the raw wool. The filling is an operation which requires discretion, if it is to be expected that the long fibres shall be preserved without breaking. The person who fills the wool on the teeth takes a greater or less lock of wool in his hand, according to the condition of it and the degree of entanglement; also in drawing it between the comb teeth, the force is proportioned to what the wool will bear. Mr. Gilpin's specification states that, under certain circumstances, when the wool will not wash well, but remains taggy, it is advisable to fill it upon the combs and slip it off, then fill it again preparatory for the machine. As the object of this first

filling is chiefly to warm the wool, the end may be in part attained by laying the wool upon the top of the stove for a few minutes before it is filled.

As we believe that the combing machines which are at present in operation, and which are not very generally shown, differ in many respects from that above described, and as we have not had an opportunity of witnessing the operation except in one case, which nearly resembled the above, we shall proceed without describing processes, which, however ingenious, are not in use, to illustrate the subsequent operations of breaking, drawing, &c., as far as they differ essentially from those described under the articles cotton and flax manufacture.

We have seen that the wool which is combed by hand is left in slivers varying from five to seven feet, but that combed by machinery is produced in one long continuous sliver; the former has therefore to undergo one process more than the other before the first continuous thread is formed: this is called planking. The slivers are rolled up by hand by the wool-combers in balls or tops, each containing ten or twelve slivers, and weighing about half a pound. These are unrolled and the slivers laid on a long plank or trough, with the ends overlapping, in order to splice the long end of one sliver with the short end of another. The long end of the sliver is that first drawn from the comb and contains the longest fibres, and the short end that which comes off last from the comb, containing therefore the shorter fibres. These ends are distinguished by the wool-comber, and the slivers are accordingly arranged by the woman or boy attendant as above described.

(1029.) *Breaking machine.*—The planking table is a part of what is called the breaking machine, represented at E, in fig. 7. Here the slivers are planked or spliced together, and are immediately drawn out and extended by the rollers of the frame, as represented in the figure.

The lower roller of the first pair of rollers receives its motion from the mill, and the roller immediately above is borne down upon it by a weight; as the motion proceeds the sliver is compressed, and is passed through the second, third, and fourth pair of rollers, which, moving with different velocities, draw out the fibres on principles very similar to those already described in the preceding articles on roller spinning, and the sliver is ultimately received into a can, as represented at C. The frame carrying the third and fourth pair of rollers is adjustable by the screw *f* to different distances, according to the staple of the wool.

The breaking and drawing frames, which are used when the slivers are prepared by combing machines, are differently constructed; these have no planking table, but receive three of the perpetual slivers from as many tin cans, or from large bobbins.

(1030.) A machine of this kind is represented in plate lxxii. fig. 5, 6, being according to a Patent taken by Mr. Lister in 1823; in which fig. 5 is a side elevation of a drawing or roving frame; B, B, B are three bobbins mounted in the usual way, each containing slivers of wool; R is a small roller partly immersed in a shallow cistern, W, of hot or cold water; P, P are two plain rollers, the upper one resting and rolling on the lower; and in order to cause a pressure between these two, a weight is hung upon the axis of the upper one. It follows from this arrangement that if the slivers S, S, S, on the bobbins B, are drawn under the roller R, they will pass through the water in the cistern W, and be thus wetted. If the

Manufac-
tures.

slivers are then drawn between the rollers P, P, a weight being hung on the axis of the upper one, the greater part of the water will be pressed out of the slivers; D, C, C, D are the carrying rollers. If the slivers, after leaving the rollers P, P, are then passed between the drawing and carrying rollers, they will arrive at the cylinders K, K, &c., the two lower of which are hollow; these are called the calendering rollers, the two upper of which are also pressed upon the lower ones by weights on their axes. The surface of these rollers are perfectly smooth and true, and the under ones being hollow may be heated by steam or otherwise, so that in the passing of the sliver between them it is calendered or hot-pressed, so as to take from the fibres any curl or frizzle; they then pass to the top of the spindle Q, and are twisted in the usual way, which is seen in the drawing, the front post of the machine being broken off to exhibit it. Mr. Lister's specification then particularizes as follows. The first motion is given to the machinery in the usual way, by means of the pulley V, over which a band is passed communicating with a competent power. On the same axis with the pulley V is a long drum M, over which bands pass to communicate motion to the revolving spindles Q, and also a pulley X, which communicates motion by means of a band to the pulley Z, which is on the end of the second calendering roller K. This roller communicates motion, by means of a wheel on its opposite end, to all the remaining rollers except R, which is turned merely by the friction of the sliver passing under it. The above description applies principally to the elevation fig. 5; some of the parts are, however, best seen in fig. 6, which is a plan of part of the machine, viz., with the upper rollers omitted. The ends of the calendering rollers K, K are represented as being supplied with screws, which are for attaching the apparatus for conducting the steam for heating them. Referring now to the description of the several motions which are traced above to the pulley Z, and the end of the second roller, opposite to where this pulley is fixed, is provided with a cog wheel, which, by means of the connecting wheels or dead centres g, g, communicates motion to the first calendering roller D. These connecting wheels g, g are arranged to allow just so much increased velocity to the calendering rollers as will keep the sliver tightly stretched; from the lower second drawing roller motion is communicated to the first drawing rollers, and from thence to the carrying rollers. To give motion to the pressing roller, an additional wheel a is placed on the axis of the first lower drawing roller, which, by means of the connecting wheel on the dead centre e, communicates motion to the large wheel f, on the axis of the lower pressing roller P. The upper rollers generally revolve by their pressure on the lower ones, except the upper calendering rollers, which are provided with cogged wheels to work in the wheels I, I, seen in the lower calendering roller, and which are used for the purpose of making their motions steady and uniform. *Repository of Arts*, vol. xlviii.

Fig. 8.

All the subsequent operations of roving, spinning, twisting, and doubling, differ only in degree from those already illustrated in cotton, flax, silk, &c., it would therefore be useless to repeat the description; it is sufficient to refer to fig. 6, plate lxix.

Weaving.

Weaving.

(1031.) In the preceding description of different
VOL. VIII.

manufactures we have only traced the several operations as far as they relate to the object of reducing the raw material into the state of yarn or thread; it remains now to explain the subsequent processes by which these threads are converted into cloth or other fabric. The yarn or thread employed in weaving is of two kinds, commonly differing considerably from each other in regard to their hardness or twist, the hardest or most twisted being used for the warp or longitudinal threads, and the softer or less twisted for the weft or transverse threads.

Mechanical
Processes.

The form in which the material is sent from the spinning and doubling or twisting mills is that of hanks or skeins; those which are to be employed as warp are now wound on to bobbins, and from these the warps are formed by the operation of what is called *warping*, which is differently effected in different manufactories, but most commonly by a warping mill, the form of which differs also very considerably. The following is not an unusual construction.

Warping mill.—Four strong posts are connected by cross pieces forming an exterior frame, (see plate lxxiii. fig. 1.) within which is a stout wooden axle with an iron toe at the bottom; this works in a cup fixed on the lower transverse beams, and an iron axle or pin above passes through a hole in the upper transverse pieces so that the axle may revolve vertically; radii proceeding from this carry eight or more long wooden rods, which form thus a large vertical reel from six to seven feet high and about the same in diameter. One of the four posts we have described is broader than the rest, or double, and on this slides freely a block of wood called a jack. This is suspended by a cord, which, passing over a pulley at the top of the post, is carried and made fast to the iron spindle or axle, so that, as the reel revolves, the jack is raised gradually from the bottom to the top, and when the mill is turned the other way it descends by its own weight, and thus carries the threads of the warp gradually up or down in order to lay them smoothly on the reel.

Warping
mill de-
scribed.
Pl. lxxiii.
Fig. 1.

The frame carrying the bobbins differs considerably according to the nature of the material which is to be warped. The method shown in the figure is the old form of silk warping. The bobbin tiers are placed vertically, but generally, in warping cotton or worsted, they run horizontally in a large frame called the travers, which will carry 100 or more bobbins. In front of this frame, that is, on the side towards the reel, are placed two long rows of glass rings, and one thread is passed through each, the threads from the upper bobbins passing through the upper rings, and the lower threads through the others. These ends are now all united together in a knot; this is passed through the runners of the jack, and thence to the mill, where it is made fast, the jack being at the bottom; the mill is then turned round by the handle attached to the bench, seen in the figure, the jack rising and distributing the warp uniformly through a certain number of revolutions equal to the proposed length of the piece of cloth, a proper allowance being made for the shortening in weaving. When the jack has risen to its proper height, the warper collects the threads with his finger and thumb, placing one of the upper and one of the lower threads alternately, and also crossing them, forming what is called the lease. These are then passed in this form over pins on the mill, and returned the reverse way over the same pins, when the motion of the mill being also reversed the jack descends, doubling thus the number of threads; at the bottom the

Manufac-
tures.

warp is again passed over pins, but the threads are not gathered alternately; the motion is now again reversed, and when at top the former operation is repeated till the proper number of threads are collected to form the breadth of the cloth, which depends of course upon the number of bobbins employed and the number of threads in the piece. The crossing of the threads is now preserved by a band tied through them at top, and the crossing of the clues at the bottom by another band, and the warp is then removed by the warper, who, generally taking it off from the lower pins, winds it round his left hand in the form of a ball, crossing and recrossing the direction to prevent its unwinding or slipping. In the case of striped goods it is the business of the warper to arrange the different coloured bobbins in their proper order to give the stripes or shades required.

Beaming.

(1032.) *Beaming*.—In the state last described the warp is received by the weaver, which is now to be wound on a large beam the breadth of the intended piece of goods. This beam has iron pivots, on which it turns. In the beaming, the weaver sometimes employs a rude sort of instrument called a separator or ravel, which consists of a number of shreds of cane fastened together and fixed to a rail of wood like the teeth of a long comb, and the alternate crossing of the several clues in the warping serve to facilitate this arrangement and to spread the warp threads uniformly over the beam in the order in which they were laid by the warper. The warp beam is marked B in fig. 2, which is a simple form of loom next to be described.

The form of looms differs considerably from each other in different manufactories, as also in their dimensions, but the general principle of construction is nearly the same in all.

Drawing.
Pl. lxxiii.
Fig. 2, 3.

Before describing the loom, however, it will be well to refer to two of its appendages, the heddles and the sley or reed; the former is represented by *aa, bb*, fig. 2, and the latter at R, fig. 2, 3. Through both these it is necessary to pass every thread on the warp beam before the operation of weaving can commence. This process is called drawing, and is thus performed: the warp being regularly wound, as above described, upon the warp beam, the weaver must pass every yarn through its appropriate eye or loop in the heddles; this operation is called drawing. Two rods are first inserted into the lease formed by the pins in the warping mill, and the ends of these rods are tied together, the twine by which the lease was secured is then cut away, and the warp stretched to its proper breadth. The yarn beam is suspended by cords behind the heddles, somewhat higher, so that the warp hangs down perpendicularly. The weaver places himself in front of the heddles, and it is the business of another person, placed behind, to select every thread in its order, and deliver it to be drawn through the open eyes of the heddles. The succession in which the threads are to be delivered is easily ascertained by the lease rods, as every thread crosses that next to it. The warp, after passing through the heddles, is drawn through the reed by an instrument called a sley or reed hook, and two threads are taken through every interval in the reed.

The lease rods being passed through the intervals which form the lease, every thread will be found to pass over the first rod and under the second, the next thread passes under the first and over the second, and so on alternately. By this contrivance every thread is kept distinct from that on either side of it, and if broken, its

true situation in the warp may be easily and quickly found; this is of such importance that too much care cannot be taken to preserve the accuracy of the lease. There is likewise a third rod which divides the warp into what is usually called *splitfuls*, for two threads alternately pass over and under it, and these two threads also pass through the same interval between the splits of the reed. These operations being finished, the cords or mountings which move the heddles are applied, the reed is placed in the lay or batten, and the warp is knotted together into small portions which are tied to a shaft and connected by cords to the cloth beam, and the yarns are stretched ready to begin the weaving.

(1033.) *Loom*.—One of the simplest of these machines is represented in plate lxxiii. fig. 2, in which *AAA*, &c. is a frame of woodwork forming the exterior of the loom. *B* is the warp beam, or that on which the warp is first wound; *aa, bb*, are heddles; these consist of threads of a particular kind fixed to the rods *a, b*; they are looped about their middle part, as will be more particularly described below, and through these the threads of the warp, as they were gathered by the warper, are passed, *viz.*, alternately through *a* and *b*; these are suspended over two pulleys *P* above, and are attached below by lines to the treadles *D, E*, so that when one treadle, for example, *D*, is depressed, the heddle *b* will be depressed also, and the other heddle *a* and treadle *E* will be raised, and by this means every thread passing through the former heddle is depressed, while the alternate threads passing through the other heddle will be raised, leaving an opening between, called the shed, for the passage of the shuttle. *G H H R* is a frame, known by different names in different towns and manufactories; it is called the *batten*, the *lay*, the *lathe*, the *boards*, &c. It swings on the upper part of the frame at *XX*, and is furnished below with a sort of framing to receive the reed *R*, the nature of which has been described in Art. 456; through this reed the threads of the warp are passed after leaving the heddles, and are thence passed to the cloth beam at the commencement of the process. The purpose of this and of the swinging position of the lay is to drive up each line of weft passed through by the shuttle to its proper closeness, according to the nature of the material in hand.

Formerly, and even at present, in many worsted looms the lower bar of the lay was only sufficient to reach from side to side of the vertical bars *H, H*, so that the weaver, reaching forward, threw the shuttle through the shed with one hand and caught it in the other, and then back again, and so on; but it is now nearly a hundred years since the fly shuttle was first invented, and for nearly that time it has been generally employed in the cotton manufacture, and certainly ought every where to be adopted. The principle of this invention may be thus described: the bottom bar of the lay is broader than the rails *H, H*, and project before their plane about an inch and a half forming a shelf called the shuttle race; the ends of the shuttle race have thin boards screwed on to form two troughs or boxes *I, I*, seen best in fig. 3, in which pieces of horn or thick leather *K, K*, called peckers or drivers, traverse. Each pecker is guided by a wire above, fixed at one end to the rails *H, H*, and at the other to the end pieces of the troughs *I, I*; this part is shown more enlarged in fig. 4. Each pecker has also a string fastened to it, tied to the handle *h*, which the weaver holds in his right hand when at work, and with which he jerks the peckers backwards and forwards alternately to the

Mechanical
Processes.

Common
looms.
Figs. 2, 3, 4

Manufactures.

right and left, and thus drives the shuttle also backward and forward through the shed.

We have already mentioned the reed R; this is fixed upon the shuttle race k, and is shut down in its place by a cap piece not shown in the figure, but which is attached to the rails H, H; this upper rail the weaver holds in his left hand, and by this means drives up the lay against each line of weft as it is thrown across by the shuttle.

Shuttle.
Fig. 5.

The shuttle, enlarged, is shown in fig. 5. It is a small piece of wood pointed at each end, from 3 to 6 inches or even to 10 or 12 inches long, having an oblong mortise in it containing a small bobbin or pin on which the yarn to form the weft is wound; the end of this yarn runs through a small hole in the side of the shuttle, called the eye, and when it is thrown by the peckers as above, it is furnished with two small wheels or runners on the under side by which it runs easily on the shuttle race, but when it is thrown by hand, these wheels are not introduced. The lines S, S, fig. 2, represent two smooth rods put between the yarns to preserve the lease and to prevent the threads from entangling; commonly for such goods as are dressed in the loom, three such rods are used. The dressing in the loom is effected by two long brushes wetted with size, one applied below and the other above, between the warp beam and the heddles, but in weaving conducted by machinery it is now done before the warp is beamed.

The entire process of weaving in this simple form will be sufficiently comprehended. The weaver seats himself upon the seat M, and applies his feet to the two treadles, alternately pressing upon one and allowing the other to rise; this opens the threads as already described; he then jerks the shuttle through from one side to the other, then with his left hand he pulls the lay towards him, and thus drives up the yarn of weft left behind by the shuttle; he then presses down the other treadle allowing the first to rise, thus crossing each alternate thread; he then passes the shuttle again, and so on, winding his cloth every now and then upon the cloth beam which draws it off from the warp beam, the friction of which is properly adjusted by the weights w, w to preserve the threads at a proper degree of tension.

Different branches of weaving.

(1034.) *Different branches of weaving.*—In the preceding part we have given an idea of the very simplest form of the weaving Art, viz., the forming of plain cloth, in which each thread of the weft passes over and under a thread of the warp alternately, two leaves of heddles and two treadles only being necessary for the purpose; but weaving in general is a much more varied Art, and in its most simple elementary division may be considered as consisting of the following distinct branches, namely, plain texture and twilling, double cloth, spotting, flushing, and cross texture. All the diversity of which these fundamental branches are susceptible arises from the manner in which the threads of the warp are separated, or the sheds opened to receive the weft. As far as we have hitherto gone the threads are opened alternately and an equal quantity of the warp is laid on each side. In other cases, the warp is laid more prominently on one side, in others the weft, in others again these changes occur at certain intervals, and in certain order, producing stripes, spots, checkered work, flowers, figures, &c.; the simplest of these forms is still produced by a certain number of heddles and treadles, and the operation of raising the figure is produced by the foot of the weaver, but in the more complicated works

recourse must be had to a draw boy, or to machinery to supply his place.

Mechanical Processes.

In all these cases the essential parts for performing the operation are the heddles, hitherto but slightly mentioned, which it will now be necessary to describe more particularly.

The heddle is differently formed for different works: some are what are called clasped, as represented at A, fig. 8; others are made with eyes, as at B; and those employed in cross textures have half heddles attached to certain parts to assist in crossing the threads of warp. The clasped heddles are chiefly in use for plain fabrics, or where little mounting is necessary: in these the threads of warp enter between the clasps, where the dot is shown in the figure; and when the warp is weak or soft in the undressed state, the clasps when drawn together prevent it in a considerable degree from being unequally strained behind the mounting. The eyed heddles are principally used in fancy works, as in these the eye passes with more facility over any obstructions which may remain on the warp after dressing. In some cases, when eyed heddles are intended for the lighter fabrics of cloth, one single knot of the twine is sufficient to form the eye, as represented in the figure at a, but for the stouter fabrics, such as the general run of customary weaving, the eye requires two knots to prevent it from slipping, as at b.

Heddles. Parts of the loom described. Pl. lxxiii. Fig. 8.

Each leaf of heddles is fastened to two shafts, one above and one below, by means of cords called the maitland cords, or backings, on which they are knotted at proper distances for the given reed, or to produce a variety of patterns from the same mounting. In fancy mountings, however, when adapted to any particular pattern, it is more advantageous to have each portion of the heddles cast or knotted on the cords opposite those spaces of the cloth which they are respectively to weave.

Different methods are employed for lifting and depressing the heddles, such as simple treadles, or treadles connected with coupers, marshes, jacks, &c.; these are severally represented in figs. 6, 7. In fig. 6, 1, 2, 3, 4 are sections of the treadles, A are the coupers, B the long marshes, C the short marshes, and in fig. 7 u and v are jacks. In all looms mounted with coupers, except those for cross warps, each leaf of heddles has its couper and its long and short marshes. The coupers are placed in the frame D, fig. 6, called the top castle, or heddle bearer, which rests on the side of the rails i i, and are kept in a horizontal position during the process of mounting by means of another small frame; the ends of the coupers, which are immediately over the centre of the loom, are connected to the upper shaft of their respective leaves by the bow cords n, n, which, in general, are tied at the distance of about one-fourth of the breadth of the web from each side. The other ends of the coupers project over the web towards the side of the loom immediately above the ends of the long marshes to which they are respectively connected by the cords e. The long and short marshes are fixed on their centres by small bolts into the marsh frame m at the opposite side of the loom. The short marshes are tied to the under shaft of their respective leaves, and in a horizontal position equally distant from the leaves and long marshes, and at a sufficient distance from both to prevent their coming in contact with the sheds when open.

Mountings with treadles, coupers, marshes, &c. Pl. lxxiii. Fig. 6, 7.

In jack mounting, A, fig. 7, is the heddle bearer, which, as in the last mounting, is supported by the side

Mounting with jacks.

Manufac-
tures.

rails or capes of the loom, which are seen in section at *i i*. B shows the two leaves of heddles, *u, v* the two pair of jacks suspended from the heddle bearer by their centres, *n* are two small rods in the under doups or bows of the two leaves respectively. When these rods are drawn up to the clasps of the heddles by the handle *o*, the clasps are opened and the threads of the warp are permitted to pass through them without obstruction. At *x* are two spring shafts which form the connection between the under shafts and their respective short marshes *y*. G is a part of the marsh frame, and *t, t* are the ends of the treadles. By examining the figure, it will appear that each jack is connected by one end to one leaf, and by the other to the other leaf, so that it would seem that one jack at each side of the loom would be sufficient for a plain fabric; but it is usual to apply two jacks at each side of these mountings for steadiness, one crossing the other, which, when the loom is at work, move always in opposite directions.

Other
forms of
mounting.

There are other methods of mounting jacks, principally with a view to facilitate the shifting back of the heddles, one of which is common, that is by what are termed tumblers, for slacking the heddles above when requisite; but the method we have described is the most simple, and at the same time equally convenient with any of the others. In order to avoid the crossing over the treadles by the weaver, in producing the required figure, different methods of arrangement have been adopted. In spot mountings, and such others as have part of their ground woven plain, the plain treadles are usually placed in the centre, and those which are destined for the figured parts at each side, as nearly as possible in equal portions. In tweels and all the varieties in which the treading is straight over the treadles, if these are numbered in order, it is plain that the right foot, when it commences the tread, will work on all the odd numbers, and the left on the even ones. Suppose, therefore, all the odd numbers to be placed together at the right side, and the even ones at the left, then the treadles may be so corded that the treading may either commence in the centre and proceed outwards, or on the outsides and work towards the centre, or, which is frequently the case, that one foot may commence at the outside and the other at the centre, and both work towards one side: thus, for example, if we take the treadles of an eight-leaf tweel whose progressive order would be 1, 2, 3, 4, 5, 6, 7, 8, then, in order to work them with both feet without crossing, they may be arranged in any of the following orders, viz.,

Order of
treading.

8, 6, 4, 2, 1, 3, 5, 7,
2, 4, 6, 8, 7, 5, 3, 1,
8, 6, 4, 2, 7, 5, 3, 1.

In some other kind of weaving, such as crapes, where one treadle works against a number, the left foot usually rests on the treadle, and the right foot works over the others in all the varieties. In other cases, when only part of the treadles can be worked alternately, as in velveteens, &c., two or more successive treadles are placed together, either for the right or left foot at pleasure, and the weaver treads these in succession with one foot and then works the other alternately. In some cases, however, additional treadles are employed to make the treading equal; and in some cases, as tweels, with an odd number of leaves, all the treadles are placed in their natural order, and the weaver works over them all with one foot; or when the treading returns in the same

natural order, as in lined work, he works over the treadles from one side with one foot, and from the other side with the other foot. It frequently occurs also, that one or more leaves are to be raised occasionally with some of the leaves which form the principal sheds. In such cases the treadles of these occasional sheds may be omitted by screwing a small piece of wood, such as a piece cut off from an old shaft, to the point of the principal treadle, and applying it to the treadle cord of these additional leaves. These attached pieces are called tongues, and while the weaver continues to work the ground, he keeps his foot on the principal treadle only, but when the additional leaves are to be raised, he slips his foot forward on the tongue and presses it down with the treadle.

Mechanical
Processes.

From what has been said, it will be seen that the more complicated the figure the greater must be the number of the leaves of the heddles, and the greater the number of treadles, while this method of opening the sheds is only had recourse to, and accordingly great ingenuity has been exercised in producing the desired effect; thus in some instances, in order to comprise as many leaves as possible in a small compass, the heddles are made of different depths, and their respective shafts raised one tier above another, to a sufficient height to prevent them from touching when the sheds are opened. For example, if a mounting were to consist of ninety leaves, which is not uncommon for some of the finer kinds of silk woven in England, and the shafts made about one-eighth of an inch thick, the whole, by arranging them in three tiers of thirty shafts each, might be comprised within the space of five inches.

(1035.) Before the invention of machines for opening the sheds of large mountings, the place of the greater number of the treadles was usually supplied by a draw boy. If the loom were mounted with couplets, the ends of all the couplets of those leaves which were to be raised from each shed were connected to a cord which descended at the side of the loom, and, passing through a hole in a horizontal board which regulated the distance of the cords, had a weight appended to it to keep it straight and to sink it after being raised. Each shed of the pattern had therefore its respective side cord, and the whole were arranged in a straight line in the hole board, in the same order as the sheds of the pattern occurred, so that the draw boy had only to pull them in succession along the board as the sheds were required by the weaver; and if to save room pulleys are employed instead of couplets, then it is evident that the cords must be selected and tied to the side cords, but in this case a small tail would be necessary.

Draw boy.

This simple mode of arranging the cords which thus open the number of sheds of the most extensive patterns woven with leaves, is inserted merely to convey to the reader a distinct idea of the general principle on which a great variety of machines have been constructed to supersede the use of the draw boy in the different branches of weaving; for however much these machines may vary in their form, or to whatever species of weaving they may be applied, still it must be kept in view that all the leaves that would have been raised by any particular treadle must here be selected and raised by the moving part of the machinery. We shall, however, only illustrate the preceding observation by a description of one of these machines of the most approved construction. Fig. 7. pl. lxxiv. is a front view of a machine called the *parrot*, from the pecking motion

Simple
substitute
for the
draw boy.

Pl. lxxiv.
Fig. 7, 8,
9, 10.

Manufac-
tures.

of that part which pulls the side or knot cords; the ends of the couplets are seen at *A*, and are numbered from 1 to 10 inclusive; the knots, or more frequently beads, which are caught by the parrot *e*, appear on the cords at *a, a*, which cords are arranged in a straight line, and kept at equal distances by the two hole boards *B, B*. At *C, C* are leads or weights appended to the knot cords, which are, in the present instance, fourteen in number. The parrot *e* is movable along the square axle *o*, and is turned round by pressing down the treadle *i*, which is attached to the wheel *D* by a cord round its rim; the cord *w* is fastened to the parrot, and after passing through a hole in the wheel *D*, it is wound about the inner part of the wheel *X*, which is turned by the hammer *E* working in its teeth. Whenever, therefore, the weaver has occasion to shift the parrot from one knot cord to another, the hammer *E* is raised by a treadle, and, falling by a weight attached to it, the cross wire *y* catches one of the teeth and moves it one tooth round; thus the length of each tooth must be such that the fork of the parrot removes exactly the distance of one bead from another. Fig. 8 is a side view of the parrot as it is mounted for a double row of knot cords, which are necessary when the sheds of the pattern are numerous; fig. 9 is a view of the wheel *D*, with the hole *z* through which the cord *w* runs; fig. 10 is a front view of the wheel *x*; *p* is another wheel on the same axle, but movable on that axis; *m, n* are two studs which regulate the number of sheds in the pattern; for when the wheel *x*, which is fixed on the axle *o*, brings the handle or index *q*, by means of the stud *n*, round to the catch *s*, which takes place always at the end of the pattern, the catch *s* is raised out of the teeth, and the weight *t*, fig. 7, draws back the parrot till the stud *n* comes round to the handle *q*, which it displaces, and allows the catch *s* to fall again into the teeth of the wheel where the pattern is to recommence. From an attentive view of fig. 7 it is easy to perceive how the couplets and knot cords are connected for each shed; for example, were the third, fifth, and sixth leaves to be raised for the first shed, each of these couplets would be connected to the knot cord No. 1, at *g*, and so for every shed of the pattern.

French
draw loom.
Pl. lxxvi.
1, 2, 3.

(1036.) It would be impossible to give a description of all the different kinds of draw looms which have been invented within the last thirty years, we shall therefore confine ourselves to one only, commonly known as the French draw loom; this has neither tails nor lashings, and the pattern, which is cut out in small pieces of pasteboard, may be changed without the weaver's stopping his shuttle. The harness of this draw loom is represented in plate lxxvi. fig. 1; it is constructed from the neck upwards similarly to the common draw loom, having knot cords arranged in nearly the same manner, but only one trap board. *E* and *A* are the carriage and uprights; *C* the knot cords, and *a* the trap board; *z* are needles or pieces of wire, one attached to each knot cord by taking a turn round it; *d* is what the weavers term a cylinder or barrel, though it is a square beam of wood, perforated with holes on each of its four sides, equal to the number of the needles employed, as exhibited in fig. 4. The barrel, besides its rotary motion, vibrates on pivots like a pendulum; *b* are small pieces of pasteboard, about ten inches long, and from two to three broad, perforated with holes to receive the ends of the needles, and are arranged agreeably to the order of the tacks in lashing the pattern for

Mechanical
Processes.

the other draw looms, as shown in fig. 3. There is one of these pasteboards for each lash; and all the boards for one pattern are connected together like an endless chain, with twine, at equal distances, so as to fit exactly the flat faces of the barrel; *g* is the receptacle for the pasteboards, which, in some looms, is composed of thongs of leather suspended from the guide *s* at one end, and from the cape of the loom at the other; in other looms it consists of parallel slips of wood connected together with cords. *D* is a lever for raising the trap board, to which it is connected by means of the circular pieces of iron *x*, one on each side, with a bar across, to the centre of which the end of the lever is connected by a piece of wire; *o, o* are cross bars of wood, with holes in their centres, through which runs pieces of strong iron wire fixed into the trap board at each side to keep it steady while in operation. At *m* are spiral springs for regulating the motion of the needles, and into the cross bar of wood *r* is inserted another piece of wood, moving on springs which yield to the pressure of the needles; these are forced back by the barrel, and recover themselves when the barrel is withdrawn; fig. 4 is an end view of the barrel with the apparatus for turning it round, which, like the rest of the machine, is extremely simple. It consists of two catches, *b, c*, which are attached to the opposite end of the frame; when the barrel is turned round from right to left, the catch *b* is lowered by means of a cord connected to a treadle, till the tooth of the catch *i* comes in contact with the corner of the barrel in its motion backwards and turns it round, till a new face and pasteboard are presented to the needles, and when it is turned from left to right, the catch *c* is employed in the same manner; *z*, fig. 1, is a cord connected to the barrel, which, after passing over two pulleys, has the direction seen in the figure, and is tied to the end of a long march; *y* is another cord which descends from the lever *D* to another long march; and these two marches are connected to separate the treadles, which are wrought alternately.

From this description of the machine its mode of operation will be obvious. The weaver presses down the treadle which pulls back the barrel *a* by means of the cord *z*, and in this state all the knot cords are drawn into the saw draughts of the trap board. As this treadle is relieved and the other pressed down, the barrel is drawn by springs against the ends of the needles, which enter into the pasteboard wherever there is a perforation; but where there is none, they are driven back, and, consequently, drive their respective knot cord out of the saw draughts of the trap board, which are then allowed to remain stationary while the others are raised.

The reading of the patterns on these pasteboards is the only tedious process connected with the machine. The method in common use is for one person to read over the tacks of the design, and another with a punch to strike out the holes in the pasteboard, agreeably to his instructions; thus on the line 1, fig. 3, there are three dots which denote three holes for the wires. The person who gives the instruction says, take three, the other person then strikes out these three holes with the punch; then, as there is a blank on the upper cross line and two on the under line at 2, three are ordered to be passed; then two on the line 2, and three on the line 3, are next to be cut out, and so on, always beginning at the bottom of the lines, as in the process of taking

Manufac-
tures.

the harness twines through a hole board. In this example there are only four cross lines or rows of holes, but in practice there are eight, corresponding to eight horizontal rows of the needles; the four small holes at each end of the pasteboards are for lacing them together agreeably to the succession of the lashes. The large holes *a, a* are made to fit the studs *a*, fig. 4, on the ends of the barrel, by which the pasteboards are drawn into their proper positions to receive the ends of the needles.—Murphy, *on the Art of Weaving*.

It is impossible within the limits of this article to give any extended view of the great variety of looms and loom mountings which the ingenuity of our manufacturers have introduced for the various kinds of weaving performed on the several different materials thus employed. In the above we have confined our remarks to the simplest operations, and must refer the reader, who is desirous of a minute and extensive description of the Art, to the Treatise by Mr. Murphy, above referred to, to which we have been largely indebted both for figures and description; and from the same ingenious author we select the following description of machinery for weaving by power.

Power loom
described.

(1037.) *Power loom*.—We have already, in our historical introduction to the Cotton Manufacture, stated some particulars relative to the invention of the power loom, and the different forms it has assumed in different manufactories, and have slightly alluded to the dressing machine, the invention of which was so necessary to the success of the attempts for weaving by power. It remains for us, therefore, only to give to the reader, in this place, a concise description of a simple machine of this kind, for which, as above stated, we are indebted to Mr. Murphy. This is represented in pl. lxxv. fig. 1, 2; the former being a front elevation, and the latter a profile. In fig. 1, *A* is the cloth; *B* the boxes of the lay; *o, o* the drivers; *c* the swords of the lay; *D* the heddles; *n* the reed; *a* fast and loose pulleys; and *i* the spring for putting on and taking off the power; 1, 2, 3, 4 are the ends of four treadles, two for opening the sheds, and two for driving the shuttle; *w* is the driving pin attached to the pulley *z*, over which there is a belt with cords attached to the two outer treadles 1 and 4; *x, x* are the wipers, and *y* the driving cord. In fig. 2, *a* is the yarn or warp roll; *b* the rods for preserving the lease; *A* the box of the lay; *c* two pairs of temples for keeping the cloth stretched; *B* a spur wheel on the axle of the cloth roll, which assists in rolling up the cloth. The fast and loose pulleys represented at *a*, fig. 1, are seen in this figure at *d*, and on the axle of these is the spur wheel *i*. The reciprocating motion of the lay *A* is given by means of the rod *e*, which connects it with the rim of this wheel, and there is a similar rod on the other side of the loom attached to a crank. The wheel *C* is driven by the wheel *i*, which, by its revolutions, drives the wipers *v, v*, fixed on its axle. These wipers act by their circumference on the treadles 2, 3; and as they are circular at their greatest distance from the centres, the motion of the heddles is thereby suspended while the shuttle is passing through the warp: on the outside of each wiper is a circular knob movable on its axis, and on the shuttle treadles 1, 4 are fixed the friction rollers *n*. When, therefore, these knobs strike the friction rollers, they give motion to the shuttle by means of the driving stick *w* and cord *y*, fig. 1. It must be observed, however, that the knobs are so fixed to their respective wipers, that the sheds

Pl. lxxv.
Fig. 1, 2.

may be fully opened before the shuttle receives its impulse; this is done by shifting them backwards or forwards in grooves cut in the wipers for the purpose. *B* and *j* are the wheels for winding up the cloth, the former being driven by a spindle on the axle of the ratchet wheel *j*, and this last is turned round by a catch attached to the top of the lever *x*; this lever has a reciprocating motion given to it by a stud in the sword of lay *s*, fig. 1; as this catch is moved by every stroke of the lay, it cannot command a tooth of the ratchet wheel at each shot, but reciprocates over one tooth till as much cloth is woven as will allow it to take hold of another tooth, the other two catches represented in the figure taking hold of other teeth alternately. The apparatus which stops the loom when the shuttle meets with any obstruction is next to be considered. Along the back of the lay *A*, fig. 2, runs an iron rod connected with a spring *g* at each end; this rod is also connected with two circular pieces of wood, one in each box in the lay, so that when the shuttle goes into the box, this piece of wood is driven back and acts upon the rod so as to raise a small plate of iron which covers a circular hole in the centre of the lay. When, therefore, the lay and shuttle are in operation, the iron plate is raised at each shot, and permits the stud *h* to pass through without obstruction; but when the shuttle flies out of the shed, the iron plate covers the hole and strikes with force against the stud *h*, which is connected with a disengaging rod, and throws the belt off the fast on to the loose pulley, which stops the loom. In fig. 3, 4, we have given a front elevation of another power loom as constructed by Messrs. Sharp and Roberts, of Manchester: its operation is sufficiently obvious from the drawing.

Mechanical
Processes.

Fig. 3, 4.

(1038.) *Double cloth weaving*.—We have said that it is impossible for us to attempt describing the various kinds of fabrics produced by the loom in a concise article of this kind. As far as we have gone the reader can form a general idea of the means had recourse to for producing plain and twilled and lined cloth and fancy work, in which the figure is found by raising different sheds, and thus leaving the weft and warp differently prominent to give the various figures; but, besides all these varieties, there are made what is called double cloth, velvets, velveteens, corduroys, cross textures, such as gauzes, linens, &c., some of which are so peculiar that a short description will be interesting to the curious reader.

Double
cloth.

Double cloth is generally composed of two similar fabrics interwoven at various intervals and formed into a diversity of figures agreeably to design of the pattern to be produced: this is the method commonly followed in carpet weaving. In some cases one of the materials is superior to the other, as in bed quiltings, in which the superior forms the face and the inferior the back, therefore, in explaining the principles of this branch of weaving, it will be necessary to refer to these methods separately. In order to comprehend more easily the first process, we may take for an example the warp of any plain fabric, of which we may suppose one thread to be blue and one white alternately, and that this is drawn through a common four-leaved set of plain heddles in the usual way; then it will appear, from the arrangement described below, that when the draught commences with a blue thread all the other blue threads will be drawn on the two back leaves at 1, 3, 5, 7, &c., and all the white threads, as numbered 2, 4, 6, &c., will be drawn on the two front ones. This is exhibited in fig. 2. pl. lxxvi., in which *A, B, C, D* represent the

Manufac-
tures.

Pl. lxxvi.
Fig. 2, 3.

treadles each connected with its respective heddles, which are denoted by the horizontal lines, and marked blue or white, according to the thread they are supposed to carry. Now,

1. When the two back leaves are raised and sunk alternately with the two fore ones and white weft thrown across, the whole fabric, which is plain cloth, will be formed in two stripes nearly entirely blue and white, and if a shot of blue and a shot of white be thrown alternately, a corresponding check will be produced. These sheds will be opened by the treadles A.

2. If the two fore leaves were constantly sunk and the back leaves raised alternately, it is plain that, by throwing in blue weft, all the blue warp would be woven into a uniform blue fabric, leaving all the white warp unwoven below. This would be effected by the two treadles marked B.

3. If the two back leaves were constantly raised and the two fore leaves raised alternately, a white fabric would be produced by throwing across white weft, leaving out the blue warp above, as marked at C.

4. And in like manner all the blue warp is sunk and white cloth woven by the treadles D.

5. The white warp is all raised and blue cloth produced by the treadles E.

By consulting the above description, and by referring to the figure, it will be manifest that each of these webs may be woven separately and distinctly from the other, either when the blue or white warp is uppermost. But the manner in which they are woven together and made to pass through each other at pleasure will be seen by what follows.

If the plan shown in fig. 3, 4, be attentively examined, it will be found that in the former, fig. 3, where the white warp is above, when the treadle marked 10 is pressed down, one blue leaf is raised and the other sunk, while all the white warp is raised above the shuttle, therefore one shot of blue weft is thrown into this shed to form the blue fabric. Now when the treadle 8 is pressed down it raises one white leaf and sinks the other, while at the same time all the blue warp is sunk quite clear of the shuttle; into this shed the first white shot is thrown; the treadle marked 9 reverses the blue shed keeping the white warp still above. Into this shed the second blue shot is thrown, and the treadle 7 sinks all the blue warp and reverses the white shed for the second white shot. The numbers on these treadles refer to those in fig. 3.

By following this process, the two webs would be woven quite distinct from each other, the white above the blue below; but when the treadles marked 4 are employed, the two webs will change places, that is, the blue web will now be above and the white below. Hence, if only one shuttle were employed for both webs, so long as the weaver continued to work upon one set of treadles, the two webs would still be distinct, except at the selvages, where they would be united by the weft.

Without entering into a more minute description, it will be obvious that, by different arrangements of the heddles and treadles, the two warps may be interwoven at any intervals at pleasure, and consequently figures of all varieties produced on either one or both surfaces. For example, referring to fig. 2, 5, the weaver may work once over the treadles marked D, by which all the white warp on the divisions A and B will be woven above, and all the white warp in the divisions C, D will be woven below, raising the blue cloth to form the figure;

and this is effected by throwing in a blue shot on treadle 1, a white one on treadle 2, a blue one on treadle 3, and a white one on treadle 4. He may then work once over the treadles C, once over B, once over A, once over B, once over C, once over D, all in the same manner as at first, after which he may continue to work twice over the treadles A and B, three times over C, four times over D, and so on agreeably to the succession of the draught, and by different arrangement patterns may be woven in great variety. See fig. 6.

(1039.) *Finishing velvets, corduroys, &c.*—These goods, after they come from the loom, have their flushed

Mechanical
Processes.

parts cut up, the former into a uniformly smooth surface, and the latter into ridges. The piece is spread for this purpose on a long table, and the person who conducts the process runs the point of a sharp instrument, called a plough, along a furrow or centre of each flushed stripe; the piece is then exposed to the action of two strong brushes which are driven across the ridges by machinery with a reciprocating motion. At each end of the table is a roller, on one of which the cloth is wound before the operation, and the other with a very slow motion receives it as it comes from the brushes. The use of this process is to raise the pile and form the cut flushing into ridges above those parts which are incorporated with the warp. When the piece has passed through this machine, the loose fibres are singed off by drawing its surface over a cast-iron cylinder made red hot. It is then immersed in hot water and well rubbed with a hand brush, after which it is dried, singed, and again put through the brushing machine, these operations being repeated three times in succession.

The piece is next put into a tub full of hot water with which are mixed a little vitriol and pearl ashes: this ley is called a *chemic*. When it is taken out of the chemic it is spread on grass, where it lies two or three days, when it is again put through the chemic and rubbed well with a hand brush to remove any fire stains or brown spots that may be remaining. Two or three days more exposure to the air on the green will prepare it for dyeing the darker colours, but for the lighter shades it will require a little bleaching.

(1040.) *Plush velvet.*—This is woven on a somewhat

Plush
velvet.

different principle to the other fabrics described above. It consists of two warps, one called the main warp or ground, which is commonly made of hard silk, and the other the pile warp. These are beamed on separate rolls, the latter being placed below the former. When the heading or end of the piece is woven, the weaver raises the pile warp, which is drawn on a separate leaf from the ground, and into this shed he introduces a wire which is longer than the breadth of the cloth. A few shots of the ground are then thrown and another wire introduced, and so on with a third. In each of these wires is a groove, along which the weaver runs the point of a sharp instrument called a *trivet*, which cuts the pile and relieves the wires in succession. The first wire, therefore, when thus relieved, is again put into the fourth pile shed, and after a few shots of the ground are woven the second wire is inserted into another pile shed, and thus the operation is continued till the piece is finished. The pile warp is commonly made of softer silk than the warp, or of a fine kind of goat's hair, and the surface of the shag is afterwards cut evenly and smooth with a pair of shears. See Murphy on the *Art of Weaving*; Duncan on *Weaving*; and various volumes of the *Society of Arts* and the *Repertory of Arts*.

Manufac-
tures.Bobbin-net
manufac-
ture.*Lace and Bobbin-net Manufacture.*

(1041.) Besides the several fabrics of cotton silk, &c. described under the article *WEAVING*, there are several others in which weaving, properly so called, is not employed; such as bobbin net, hosiery, &c., to which we shall refer, but these branches are so numerous that we can only select one or two. The most important are those above named, and the former in particular is so illustrative of the advantages of machinery, and of the success of well-directed ingenuity even in the most difficult processes, that we cannot pass over this almost infant Art without endeavouring to give to the reader some idea of the process, and of its importance in a national point of view.

Bobbin net is a species of plain lace of a transparent texture, a fabric which, till within a very few years, was made at so slow a rate that it could only be used by the very highest classes of Society; and in order to show more prominently the extent of ingenuity which must have been exercised in the invention of machinery for this purpose, it will not be out of place to give a slight description, in the first instance, of the original method of forming the different kinds of lace on cushions.

Making
pillow lace.

(1042.) This was commonly made of thread or silk woven into a net, the meshes of which were varied in their figure according to the design of the pattern, as into hexagons, octagons, &c. This was also ornamented by a thread much thicker than the rest, so interwoven within the meshes as to form flowers, curves, and other figures, upon the beauty and elegance of which, and the uniformity of the meshes themselves, the value of the lace depended. This thick thread is called *gimp*.

The pillow or bobbin lace is made on a pillow or cushion by women and children, principally in this Country in Buckinghamshire and Bedfordshire. The operator places the cushion on her knees; the threads are wound upon bobbins, which are small round pieces of wood about the size of a pencil, round the upper edge of which a deep groove is formed so as to reduce the bobbin to a thin neck; and on this part the thread is wound, a separate bobbin being used for each thread. To give form to the meshes, pins are stuck into the cushion, and the threads are woven and twisted together around the pins; a piece of parchment is first fixed down upon the cushion, which has been previously pierced with small pin holes, to show the proper places for the pins, and on this parchment the design for the gimp or thick thread is also traced, to guide the woman in placing the gimp, so that it will be woven in between the fine threads which form the network. The work is begun at the upper part of the cushion by tying the threads together in pairs, and each pair is attached to a pin which is stuck through the parchment into the cushion. The round form of the cushion allows the bobbins to hang down by their threads on different sides, and on whatever side the bobbins are placed they will continue. At the commencement of the work all the bobbins are put on one side of the cushion, and are brought to the front side, four bobbins, or two pairs at a time, to be twisted together. The woman takes one pair in each hand, and with the finger and thumb twists the bobbins over each other three times; the effect of this is to twist the threads of each pair together, or round each other, and this is done by both hands at the same time. When the twisting, which forms the sides of the mesh, is thus completed, the adjacent bobbins of each pair are interchanged, in order to cross the threads

of those bobbins over each other, and make the bottom of the mesh. To render this clear, suppose the four bobbins numbered: No. 1 is twisted round 2, and 3 is twisted round 4; then, in order to cross, 2 and 3 are interchanged, so that 1 and 3 come together, and 2 and 4; and the next time that the twisting operation is performed these pairs of threads will be combined together.

When a mesh or half a mesh is made, it must be secured by putting a pin into the cushion; and in order to draw the twist work close, the pin is introduced between the recently crossed threads, and carried up towards the top of the pillow, so as to drive the twists and cross before it, and concentrate or draw the twists into a small compass; the pin is then inserted into its proper hole in the parchment, which prevents the threads from returning. These four bobbins are now done with for the present, and are put on one side of the cushion; then the two next pairs are brought forward into the front of the cushion, and are twisted and crossed in the same way; in this manner the work proceeds, till a row of meshes is formed all across the breadth of the intended piece of lace, and then the same bobbins are worked over again to make another row. In general, the number of bobbins and of threads is equal to 48 or 60 to every inch of breadth.

The work people perform these operations with great dexterity; but the work, nevertheless, proceeds very slowly, as it requires so many meshes to make a small piece of lace, and only one mesh is made at a time. Taking the threads at 50 per inch, if the piece of lace is one inch wide, it will have 25 meshes in the breadth, or 625 meshes in each square inch of length, or 22,000 meshes in a yard; and the price of a piece of lace of this description is seldom more than eighteen pence.

(1043.) This is sufficiently illustrative of the old form of lace-making; it will also give the reader an idea of the immense difficulty to be overcome before this process could be successfully imitated by machinery. The first attempt, it appears, was made about 1764 or 1770, when a machine was brought from Switzerland; and various attempts were made to improve it so as to produce a sort of plat, but the operation was found to be so slow and imperfect that it was soon abandoned. The next step towards the accomplishment of the object was the warp frame, which is a variety of the stocking frame, although the parts are differently arranged, all the movements being adapted to be produced by treadles, leaving the hands of the workman free to manage the machine, which is a piece of mechanism applied in front of the frame. Here the piece of lace is not formed of one continued thread as in the machine last referred to, but there are as many threads as there are needles in the frame; these are warped or wound upon a roller or beam, the same as the loom, and it is from this circumstance that the machine is called the warp frame, the former being denominated the point-net frame. The lace thus formed was more permanent than that of the point-net frame, and the process was quicker, but after all, this kind of lace never commanded great attention as an object of fashion.

(1044.) At length, in 1808, a Patent was taken out by Mr. Heathcoat, for the manufacture of what is now called bobbin net, which, it is said, originated by a workman, employed in making machinery for producing fishing-nets, seizing upon a hint which accident threw in his way, which led to the idea of making lace by warp and weft. The groundwork of the invention is to extend those threads which form the warp of the lace in parallel lines and to dispose the diagonal threads upon small bobbins

Mechanical
Processes.Application
of ma-
chinery.Heathcoat's
Patent
for bobbin
net.

Manufac-
tures.

which are detached and capable of passing round the extended warp threads so as to twist with them. By this means the number of bobbins is reduced one-half. There are two horizontal beams or rollers, one to contain the thread, and another to receive the lace, and a number of small bobbins to contain the weft thread.

These bobbins resemble the quills or pirns used in a weaver's shuttle, but are made very small, each bobbin being only a wire pin, round which the thread is lapped in the form of a small cone, and a slender spring is provided to cause just so much friction as will make the threads draw tight when pulled off from the bobbin. One of the rollers above mentioned is placed in the under part of the machine, and the other in the upper part, both in the same perpendicular plane; the threads intended to form the warp or longitudinal threads in the piece of lace are wound upon the lower roller and ascend to the upper, to which they are separately attached.

The bobbins are so arranged between these two rollers that the threads proceeding from them accompany the longitudinal threads to the upper roller and are attached thereto. Each of the longitudinal threads, in its way to the upper roller, passes through a conical tube, at the lower end of which is a small spindle, which is so supported as to admit of being turned round. On the upper end of the spindle is a taper tube, composed of two parts, which open longitudinally; one of the parts so divided remains attached to the spindle, and is thus sustained, partaking of the revolving motion of the latter; and the longitudinal thread which passes through the spindle is conducted through the hollow part of this half tube, and through a small eye at the extreme point of it. The other section of the tube, which, as has been said, can be separated from the spindle, contains within its hollow part the small bobbin on which the diagonal thread is wound; so that when the parts are placed together, each tube contains two threads, one the warp thread proceeding from the lower roller, and the other from the pirn or bobbin containing the weft thread enclosed in the movable half of the tube.

These spindles are mounted in collars, so as to be capable of turning round by means of the pinion at the lower extremity, and when so turned will twist the bobbin and longitudinal threads together. The number of these tubes or spindles is just equal to the number of pairs of each kind of threads, and their arrangement is such that all the pinions lie in the circumference of a circle, and the spindles and tubes converge towards the centre of the same circle as so many radii. The pinions can be all moved round at the same time by rackwork, the teeth of which correspond with the pinions. This motion is to cause the pair of threads contained in each tube to twist together, and this twisting, as is obvious from the description, taking place at the same time in all.

The crossing the diagonal threads, which is the next step, is performed at once in the whole breadth, as follows. That movable part of each divided tube which contains the bobbin of diagonal thread, or weft, is removed from the other portion by a very ingenious piece of mechanism, and brought forward altogether till they are entirely clear of the spindles; and during this time one half of them are caused to move one space to the right, and the other half one space to the left. The sifted parts are then put back again and attached to the spindle, but not to the same spindle, so that by this motion each spindle will have changed its diagonal thread,

VOL. VIII.

but the parallel or warp thread will remain. This effects the crossing of the threads throughout the whole breadth of the machine at the same time. Mechanical Processes.

The pins by which the uniformity of the meshes is preserved are all placed upon a movable bar, and are all inserted at once into the meshes formed by the two operations of twisting and crossing. The working of the machine is a constant repetition of twisting, crossing, and taking up the meshes.

This was the first successful attempt at bobbin-net weaving, (as it may without much impropriety be called;) it was much improved again by the inventor in the following year, when, instead of the limited breadth of lace which only could be formed by the machine last described, pieces might now be made of any breadth required. A Patent was secured, and it turned out a very successful speculation to those concerned, as well as a great advantage to the inhabitants, who thus found useful employment both for themselves and children. Important improvements in this process have, however, been made since the expiration of the Patent, which has enabled the present manufacturers to sell for half-a-crown that for which the original Patentees obtained five guineas. Subsequent improvements.

(1045.) This manufacture, so recent in this Country, has already extended to immense importance from the amount of capital it involves, and the number of hands which it employs, as will be seen by the following statistical view of it by W. Felkin, Esq., showing its state in 1831. Statistical view of the net trade.

Capital employed.

35 factories for spinning and doubling, principally in Manchester, value	£ 460,000
682,000 spindles and other machinery	375,000
Spinners' and doublers' stocks	100,000

Manchester total capital about £935,000

Capital employed in Bobbin-net Making.

22 factories, principally for power machines, value	80,000
Increased in two years, one-eighth in number, and one-sixth in capacity for production, 1000 power machines, average 10-quarter wide	150,000
Increased in two years, one-eighth in number, and one-sixth in capacity for production, 3500 hand machines, average 8-quarter wide	390,000
Stock on hand, power owners...	250,000
Ditto, hand ditto	150,000
	£1,020,000
Capital in embroidering, preparing stock ...	355,000

Total capital employed about £2,310,000

Its extensive influence is seen by the number of hands employed.

In Manchester, spinners (adults)	3000
Children	6000
Manchester and Nottingham doubling ..	4000
	13,000
In power-net making (adults)	1500
Ditto youths of fifteen or more ...	1000
Ditto children	500
Carried forward ..	3000
	13,000

5 c

Manufactures.

Brought forward	3000	13,000
In power-net making, women in mending	2000	
In hand-machine working, nearly all men, only a few apprentices of fifteen or more, almost all at home, in shops.	5000	
Ditto children winding at home	4000	
Ditto children mending at home	4000	
		18,000

In embroidering, in almost every village within a circle of fifty miles round Nottingham, in Glasgow, Ireland, London, Devon, Somerset, and Norfolk, (women and children)	150,000
In mending, pearling, finishing.	30,000

Total number of persons receiving wages 211,000

The population of Nottingham, Lenton, Beeston, Radford, Barford, Arnold, and Snenton, in 1811, (the epoch of the commencement of the bobbin-net manufacture,) was 47,300, the present number of inhabitants is 79,000. The hosiery trade employs fewer hands in these towns now than it did then, and the point-net trade has much declined. No other branch of business has materially advanced or sprung up in the mean time, therefore this large increase of population may be fairly attributed to the bobbin-net manufacture. Besides this surplus 32,000 persons, a large proportion of the remaining population of this town and neighbourhood is dependent upon and chiefly employed in its various operations.

As a peculiar excellence of this trade, it may be remarked that, while 150,000 embroiderers are mainly dependent upon this employ, and work regularly, there are many others who are employed only at intervals of rest from household or other labour, the wages therefore go in aid of other trades half over England, and any diminution in this causes proportionate distress in other cases.

The advantages are again seen in a very prominent point of view, by the comparison of the value of the raw material when imported with the value of manufactured goods therefrom; thus the amount of Sea-island cotton annually used is 1,600,000 pounds, value £120,000. This is manufactured into yarn, weighing 1,000,000 pounds, value £500,000.

There is also used 25,000 pounds of raw silk, which costs about £30,000, and is doubled into 20,000 pounds thrown, worth £40,000.

The Cotton is worked into

6,750,000 square yards of net, worth 1s. 3d. per square yard, being on an average coarse 11-point, and nearly all in plain net...	421,875
15,750,000 square yards of hand net worth 1s. 9d. per square yard, being on an average fine 11-point, and two-thirds in quillings ..	1,378,125
150,000 square yards of fancy net, worth 3s. 6d. per square yard.	26,250

The Silk is worked into

750,000 square yards of silk net, worth 1s. 9d. per square yard	65,625
23,400,000 square yards, annual produce of bobbin net, of the present value of	£1,891,875

The brown nets, which are sold in Nottingham market, are in part disposed of by the agents of twelve or fifteen

of the larger makers, *i. e.* to the amount of about £250,000 per annum. The principal part of the remainder, *i. e.* about £1,050,000 a-year, is sold by about two hundred agents, who take the goods from one warehouse to another for sale.

Of this production, about half is exported in the unembroidered state, and in the white principally; yet a large quantity is sent in the unbleached state, and is embroidered abroad, and much is figured in the white on the Continent. So that it is probable that as much is figured abroad as at home, and this principally on account of wages being lower there than here, notwithstanding the low rate of embroidery earnings in this Country. This foreign embroidery is chiefly done in Belgium, Saxony, and, until recently, in Poland. The exports of bobbin net are in great part to Hamburgh, for sale at home, and at Leipsic and Frankfort fairs, Antwerp, and the rest of Belgium, to France by contraband, Italy, and North and South America. Though a very suitable article, yet the quantity sent Eastward of the Cape of Good Hope has hitherto been too trifling for notice. Three-eighths of the whole production is sold unembroidered at home, the remaining one-eighth of the half kept in this Country is embroidered, and increases the estimated value as under, *viz.*

Embroidery on power net increases value £131,840, and is ultimately worth £553,715.

Embroidery on hand net increases value £1,205,860, and is ultimately worth £2,583,985.

Embroidery on fancy nets increases value £78,750, and is ultimately worth £105,000.

Embroidery on silk net increases value £109,375, and is ultimately worth £175,000.

Total embroidery wages and profit, £1,525,825.

Ultimate total value, £3,417,700.

From this it appears that, in the operations of this trade, which had no existence twenty years ago, £150,000 original cost of cotton and silk becomes, when manufactured, of the ultimate value of £3,417,700 sterling.

There are about seventy houses engaged chiefly in embroidering goods, and as many engaged in the preparation and sale of plain goods principally. The cash paid to small owners for the purchase of hand nets about equals the amount of capital created by the credit given to this market by power-net manufactures.

As to weekly wages paid, the following is hazarded on the judgment of those conversant with the respective branches, *viz.*

In fine spinning and doubling, adults 25s., children 7s., work twelve hours per day.

In bobbin-net making, men working machines, 18s. apprentices, youths of fifteen or more, 10s.; by power fifteen hours, by hand from eight to twelve hours, according to width.

In mending, children 4s., women 8s., work from nine to fourteen hours, *ad libitum*.

In winding, threading, &c., children and young women 5s., irregular work according to the progress of the machines.

In embroidery, children seven years old and upwards 1s. to 3s., work ten to twelve hours; women, if regularly at work, 5s. to 7s. 6d., twelve to fourteen hours.

As an example of the effect of the wages of lace, embroidery, &c., it may be observed, it is often the case that a stocking weaver in a country village will earn only 7s. per week, and his wife and children 7s. to 14s. more at the embroidery frame.

Mechanical Processes.

Manufac-
tures.

On the subject of health, fine spinning and doubling is not so injurious as is generally supposed. In bobbin-net power factories, the rooms are not hot and confined, the lads are healthy, having, like men, only to superintend, not to work the machines. To interfere with them by any legislative act seems unnecessary, and therefore injurious in its effects.

In hand-machine labour, which is heavy compared with that of stocking and most other machines, two hands work most of the wide machines in four-hour shifts. Their health has hitherto been good, but owing to the late depression of twenty-five per cent. in wages, and thirty-five per cent. in prices, increased exertion is made by the hands, and it is very probable that further depression in wages will cause material deterioration in the general health of the hand workmen, especially those engaged in wide machines.

The principal part of the hand machines are worked in shops, forming part of or attached to private houses. The subjoined list will show the ownership and kinds of machinery now at work in the bobbin-net trade.

The health of the lace embroiderers, owing to their leaning over the running or embroidering frame, is frequently impaired; for where there is predisposition to pulmonary diseases or indigestion, it is brought into activity, and slight distortion of the body is common amongst those regularly and closely employed. It is the concurrent testimony of all those authors consulted, that, the tender age of female children when they begin to be employed being considered, the hours of working are too long; however, being domestic employ, and voluntary on the part of the parents of the children in question, or of the young persons themselves, it is difficult to interfere.

The following shows the change from 1831 to 1833.

Capital employed in spinning and doubling the Yarn.

Fixed capital in 35 spinning and 24 doubling factories, £460,000 spinning, £255,000 doubling spinners	£715,000
Floating capital in spinners' and doublers' stock, and necessary sundries	200,000
	£915,000
Deduct one-sixth employed for foreign bobbin-net trade	155,000
Total capital employed in spinning and doubling for English bobbin-net trade	£760,000

Capital employed in Bobbin-net Making.

Fixed capital in 25 factories, principally for power machines	£85,000
Fixed capital in 1100 power machines, averaging 11-quarter wide	170,000
Fixed capital in 3900 hand machines, averaging 9-quarter wide	267,000
Floating capital in stock	£
on hand-power owners	150,000
Floating capital in stock	£
on hand owners	250,000
	400,000
	922,000
Capital in embroidering, preparing, and stock	250,000
Total capital employed in trade	£1,932,000

Mechanical
Processes.

The following number of hands are employed:

In spinning, adults 4800, children 5500	10,300
In doubling, adults 1300, children 2000	3,300
	13,600
Deduct one-sixth employed for foreign demand	2,300
	11,300
In power-net making, adults 1500, youths 1000, children 500, women and girls in mending 2000	5,000
In hand-machine working, small machine owners 1000, journeymen and apprentices 4000, winders 4000, mending 4000	13,000
Mending, pearling, drawing, finishing, &c. ...	30,000
In embroidering, at present very uncertain, probably about	100,000
Total of hands employed	159,300

Value of the raw Material when imported, and of the Goods manufactured therefrom.

Amount of Sea-island cotton annually used 2,387,000 pounds, value before the late advance £179,000, but now worth £224,000. This is manufactured into yarn, weighing 1,532,000 pounds, value £766,000. But of this quantity 262,000 pounds are sent abroad, leaving 1,270,000 pounds; value before the advance £635,000, and since the advance worth £680,000. This yarn (inclusive of about £10,000 worth of thrown silk) is worked up into

5,645,000 yards of hand lever quilling net, averaging, fine 11-point, at 1s. 3d. per square yard, £352,815.
2,207,000 yards of hand circular quilling net, averaging, fine 11-point, at 1s. 3d. per square yard, £137,935.
6,622,000 yards of hand circular plain net, averaging, fine 12-point, at 1s. 6d. per square yard, £496,650.
4,580,000 yards of hand rotary plain net, averaging, common 11-point, at 1s. per square yard, £229,000.
10,905,000 yards of power plain net, averaging, common 11-point, at 1s. per square yard, £545,250.
562,000 yards of fancy net, at 2s. 6d. per square yard, £70,250.
250,000 yards of silk net, at 1s. 6d. per square yard, £18,750.

Total square yards 30,771,000, annual produce of English bobbin net, of the present value, £1,850,650.

Two years ago there was much fine yarn on hand, and many mills were then standing, or only worked three or four days a-week; all these, and many others, are now, 1833, in full occupation, their production being regularly absorbed by the actual demand, for there are now no stocks of fine yarns here, or on the Continent; and while an advance has taken place in coarse yarns equal to the rise in the price of cotton wool, none has yet taken place in fine yarns in the market.

By comparing this calculation with that of 1831, when 23,400,000 square yards, the then annual produce, were worth £1,891,875, it will be seen that, while there is a difference in favour of the machine owners and workmen, in the smaller proportion of quillings to plain nets now made, and in the advantageous use of much new and improved machinery, yet, on the other hand, they are producing 7,000,000 of square yards per annum more than at that time, for

Manufac-
tures.

about the same amount of wages and profits; the number of cotton now used being on an average as fine, and its price as high, at the period when that calculation was made. The average fall in the price of bobbin net has been twenty per cent. It is probable that about £550,000, or little more than one-third of what was paid in 1831, may have been paid for English embroidery during the last twelve months. Since that period the embroidery put on bobbin net, both at home and abroad, has been of much less expensive quality than heretofore, as well as at greatly reduced wages, which will account for part of the great diminution here stated, and decreased demand explains the rest. Foreign embroidery on bobbin net is annually on the increase, and likely to continue so.

Of late, three-fourths of our production have been exported, and chiefly in the plain state. The American trade, which has much increased, is supplied entirely in the white. Quillings are sent to the North of Europe in the white, as are also the principal parts of wide nets sent to those markets. A large quantity of wide net is sent into Belgium and into France in the unbleached state. We have almost entirely ceased to export quillings into France, as they make an immense quantity themselves. Recently, increased impediments have been thrown in the way of the introduction of bobbin net into France, as also of the English yarn, the latter to satisfy the French spinners, the former the makers of net. The demand for quilling from Germany has also materially declined, and many houses are giving up dealing in the article.

English Bobbin-net Machinery.

Hand levers, 5 and 6-quarter, 500; 7-quarter, 200; 8-quarter, 300; 10-quarter, 300; 12-quarter, 50; 16-quarter, 30; 20-quarter, 20.	
Hand rotary, 10-quarter, 100; 12-quarter, 300.....	1,800
Hand circular, 5 and 6-quarter, 100; 7-quarter, 300; 8-quarter, 400; 9-quarter, 100; 10-quarter, 300; 12-quarter, 150	1,350
Hand traverse, pusher, and straight bolt, average 5-quarter	750
Total hand machines	3,900
Power 5, 6, and 7-quarter, 90; 8-quarter, 350; 10-quarter, 280; 12-quarter, 350; 16-quarter, 30	1,100
Total number of machines ...	5,000

The wages paid in fine spinning are, for adults, from 8s. to 40s., and perhaps may average 17s. per week; children from 2s. 6d. to 7s., averaging about 5s. In doubling, adults from 8s. to 30s., averaging about 12s.; children from 2s. 6d. to 7s., averaging about 4s. 6d.

In bobbin-net making, men 18s., apprentices 10s., boys 5s. In mending, winding, threading, &c., children 4s., women 8s. In embroidering, children 1s. to 2s., women 3s. to 5s. per week, working twelve to fourteen hours. During the last two years, an extraordinary depression has taken place in the demand and wages paid for embroidery, chiefly arising from competition with Belgic and Saxon embroidered goods. Wages are lower in those Countries than they have been here, though our good hands were reduced to 2s. 6d. or 3s. a week, for women's wages. Many have left the business in despair, and a considerable reaction has taken place, so

that hands are now scarce at the rate above quoted. It is difficult to ascertain with any exactitude the number at present employed. Mechanical Processes.

Wages were reduced in 1830 and 1831, say twenty-five per cent., or from 24s. to 18s. a-week, and machines had increased in the same time one-eighth in number, or from 4000 to 4500, and one-sixth in capacity of production. It has also been stated to be deserving the serious notice of all proprietors of existing machines, that new ones were introduced into the trade, of such power of production as must still more than ever depreciate the value of their property, have a direct tendency to sink the small owners into journeymen, and either greatly increase the labour or depreciate the wages of the workmen. The machines that have since been built, if worked by three men, in six-hour shifts, or eighteen hours per day, would each turn off 20,000 square yards of good net per annum. The result then predicted has actually occurred; the wages per week have been much lowered, although the weekly earnings are now about the same as in 1831. The inferior machines are single-handed, and the journeymen are working either wider or speedier machines than heretofore, so as to produce probably a fourth more net.

Such was the state of this important trade in 1831 and in 1833; and although it is much to be regretted that the wages of those employed do not appear to keep pace with the increased demand, yet the value of the manufacture, looking at the immense sums paid in wages altogether, cannot but be considered very important, particularly when it is considered that only twenty-five years back it had not sprung into existence.

Hosiery.

(1046.) Hosiery is a term originally applied to express the article of dress which covers the feet and legs, but it now is understood to comprehend generally all articles made by knitting, or with a frame producing a similar stitch. The Art of knitting is by no means of ancient date; the hose or stocking having been, up to the time of Henry VIII., made of milled cloth by tailors. It seems probable also, that the first knit stockings were of silk, although the same process soon became common with other materials. At all events, there are but slender grounds for placing the Art of knitting earlier than the commencement of the XVIth Century; and there is sufficient evidence that, up to nearly the beginning of the XVIIth Century, cloth hose, made by tailors, were not uncommon. It is stated by Dr. Howell that Henry VIII. occasionally received knit silk stockings from Spain; that Edward VI. was presented with a pair of long silk stockings by his merchant, Thomas Gresham, which present was taken great notice of; that Queen Elizabeth received a like present from her silk woman, Mrs. Montague, and that she never after wore any other. At the same time other proofs are given that, however novel the Art of knitting might be in the beginning of the XVIth Century, it was by no means uncommon towards the end of it; for it is recorded that, about the year 1570, only nine years after Elizabeth had received the aforesaid present, on her visit to the city of Norwich, several female children appeared before her, "some of whom were spinning worsted yarn, and others knitting it into yarn hose, or stockings."

It would be uninteresting and unprofitable to pursue an inquiry relative to the Art of knitting, or to attempt

Manufac-
tures.

to describe in words what is so commonly practised and so well known, although no longer for any thing more than mere amusement; for the Art of stocking weaving enables the workman to produce his article so quickly, that knitting, as a means of profitable employment, has been long laid aside, except in such places as are far remote from the localities of other manufactures, which generally furnish to women and children a much more active and desirable occupation.

Invention
of the
stocking
loom

Stocking frame or stocking loom.—It is observed by Beckmann, in his *History of Inventions*, that the stocking loom is worthy of particular admiration, as it was not, like many great discoveries, the result of accident, but the reward of well-applied talent and genius. It is an exceedingly complicated machine, consisting, according to the quality of the article, of many hundreds, even thousands, of moving parts, which in an instant almost can make a hundred or two hundred meshes, without requiring much skill or labour on the part of the workman. It is also remarkable that it so soon followed the Art of knitting, and that but little improvement was made on the original machine for a period of about 170 years. There is also another peculiarity attending the invention of the stocking loom, viz., that there seems to be comparatively little or no dispute concerning its original author, or the period of its introduction, this honour being almost universally given to William Lee, in the year 1589.

It appears by Beckmann, *History of Inventions*, vol. iv., that, under the administration of Cromwell, the stocking knitters of London presented a petition in which they required permission to establish a guild. In the petition they gave the Protector an account of the rise, progress, and importance of their Art or trade; and there can be no doubt that this document, which is well written, contains the oldest authentic information in regard to this invention, which was then scarcely fifty years old. On this account every thing must have been fresh in the memory of those by whom it was drawn up, every circumstance could then be easily examined, and the petitioners must have been sensible that any misrepresentation they might make could be readily contradicted. An account of this petition is given by Deering in his description of Nottingham, where the loom was first employed, and where it has since enriched many families, and from which place the use of it has spread throughout almost every part of England and of Europe. From these details of Deering it appears that the real inventor

by William
Lee, in
1589.

was William Lee, whose name in the petition was spelled Leea, a native of Woodborough, in Nottinghamshire, a village about seven miles distant from Nottingham. He was heir to a considerable freehold estate and a graduate of St. John's College, Cambridge. It is reported that, being enamoured of a country girl, who during his visits paid more attention to her work (which was knitting) than to her lover, he endeavoured to find out a machine which might facilitate and forward the operation, and by these means afford more leisure to the object of his affections to converse with him. In the Stocking Weavers' Hall in London is an old picture, in which Lee is represented pointing out his loom to a female knitter who is standing near him, and below it is an inscription with the date 1589. The inventor instructed his brother James in the use of the loom, and took apprentices and assistants, with whom he carried on business for some years at Calverton, a village five miles distant from Nottingham, from which circumstance this village has been erroneously

considered as the place of his birth. He showed his work to Queen Elizabeth, and requested of her some support or remuneration; he, however, obtained neither, but was impeded rather than assisted in his undertaking. Under these circumstances, Lee accepted an invitation from Henry IV. of France, who had heard of this invention, and promised to give a handsome present to the author. He therefore carried nine journeymen and several looms to Rouen, in Normandy, where he worked with great approbation; but the King being assassinated, and internal commotions taking place, Lee fell into great distress and died soon after in Paris. Two only of his people remained in France, who were living when the above-mentioned petition was presented to Cromwell; the other seven returned to England, and these, with a person named Aston, who was one of Lee's apprentices, laid the foundation of the stocking manufacture in Nottingham, London, and other parts of England. The number of masters increased so much in London in the course of fifty years that they wished to be united into one guild, as above stated, which, however, for some reasons not known, was refused by Cromwell; but in 1663 they received Letters Patent, which gave them certain privileges to the extent of ten miles round London.

Mechanical
Processes.

In the year 1614, the Venetian Ambassador persuaded an apprentice, Henry Mead, by a promise of a present of five hundred pounds, to go with a loom to Venice for a stated time, and to teach the use of it in that State. Mead met with a favourable reception in the city, and was much admired; but the loom becoming deranged, and no person in Venice being able to repair it, when the time of his agreement was expired he returned to England. The Venetians had not sufficient resolution to continue the attempt, and sent the damaged loom, together with some bad imitations of it, to England, where they were sold for a mere trifle.

This account, which is contained in the petition above referred to, is contradicted by some Italian authors; it is, however, very consistent with the known difficulty of making and repairing the stocking frame even to the present day. The number of moving parts is so great, and the compass of their action so small, that the slightest bending of the needles, or the slightest derangement, renders the whole machine unserviceable; a circumstance which has given rise to a class of workmen called *setters-up*, whose business is to put in order any frame which, by accident or ill usage, has been deranged: these are not the frame smiths; but have about the same relation to them that the tuners of the piano-forte have to the makers of that instrument.

The Italian writers, however, deny this statement, and maintain that the Ambassador above referred to brought two stocking weavers to Venice, that he placed under them four apprentices, and when these two went back to England he sent with them a boy who returned to Venice well instructed in the Art, and who continued to carry on business there with great success; and that Giambaptista Carli of Gerona, a smith who worked in steel, saw the loom at Venice, which had been made after the model of those brought from England and sold to Francesco Alpruni of Udino; that, in a short time, he made other frames; and that a great many stockings were manufactured there and sent for sale, chiefly to Austria. But in consequence of the poverty thus brought upon the Venetian stocking knitters, an order was issued that Carli should make no

Manufac-
tures.

more looms; and this productive branch of business at Udino was, in consequence, so much deranged that the masters removed with their looms to Gradisca, where the inhabitants of Udino were obliged to purchase such stockings as they had occasion for. It appears further that, some years after this, one Abraham Jones carried the stocking weaving to Amsterdam, but that, in a short time, he and his assistants were carried off by a pestilential disease, and that these looms were returned to England, no one in Amsterdam knowing how to use, and much less how to repair them.

French
claim to the
invention.

We have said the honour of this discovery was without dispute due to Lee, but it ought rather to have been said that it was undoubted, but not entirely undisputed; and that we may not be supposed to take a partial view of the case, it may be well to conclude our sketch with a quotation from Beckmann, who observes, after stating many of the preceding facts, "It appears to me, therefore, proved beyond all doubt, that the stocking loom was invented by William Lee about the end of the XVIth Century; and this is admitted by some French writers, such as Voltaire and the Editor of the *Encyclopédie*, whom the author of the *Encyclopédie Méthodique*, however, finds fault with. Other French writers, who are the more numerous party, wish to ascribe the honour of this invention to one of their own Countrymen, but the proofs they bring are so weak that they scarcely deserve any notice. Savary is perhaps the first person who ventured to support this instance of Gallic vanity; at all events, he is quoted by the more modern writers as their authority when they wish to contradict the English.

"According to his account a Frenchman, of whom, however, he knows nothing further, invented the stocking loom, but not being able to obtain the exclusive privilege of using it in his own Country went to England. The utility of it being soon discovered there, it was forbidden, under pain of death, to carry the loom, or a model of it, out of the Kingdom. But another Frenchman, respecting whom he is equally ignorant, having seen the loom, the form of it made so strong an impression on his mind that, on his return, he copied it exactly, and from this loom all the others made in France and Holland were constructed. Savary adds, 'Did the invention belong to the English, who are accustomed to pay due honour to those who discover useful things, they undoubtedly could tell the name of the inventor, which, however, they are not able to do.' It is very strange that this should be written by a Frenchman, who himself did not know the name of the French inventor, or of the person who carried back the invention. No order to prevent the exportation of the stocking loom was issued in England so early as Cromwell's time, otherwise it would certainly have been mentioned in the petition presented to him. It was not till the eighth year of the reign of William III., that is, 1696, when looms were every where common, that the exportation of them was forbidden, probably because the best were made in England, and it was wished that the gradual improvement in them should be kept a secret.

"Some have endeavoured to give an air of probability to the above assertion of Savary, by the relation of an apothecary in the Hôtel Dieu at Paris. This person is said to have declared that the inventor was a journeyman locksmith, in Lower Normandy, who gave a pair of silk stockings, his own workmanship, to Colbert, in order that they might be presented to Louis XII.; but as the *marchands bonnetiers*, who

dealt in articles knit after the old manner, caused several of the loops of these stockings to be cut by some of the servants at Court, whom they had bribed for that purpose, they did not meet with approbation. The inventor was so hurt by this disappointment that he sold the loom to an Englishman, who died an old man in the Hôtel Dieu, where the apothecary became acquainted with him. It was necessary to expose the lives of many workmen, and even some men of learning, in order to bring back the loom to France. Romé de la Platière adds that he heard at Nismes that, in the time of Colbert, a person of that place, named Cavallier, carried the first loom to France, and that in the course of fifty years the number of them in that town and neighbourhood increased to some thousands. It appears much more probable, however, as Savary asserts, that the stocking manufacture was established at the castle of Madrid, in the *Bois Boulogne*, near Paris, in the year 1656, under the direction of John Hindres." Beckmann, *History of Inventions*, vol. iv.

It must be seen, however, after all, that the whole of this French history is void of any written document or authority, and is at variance with itself, and that it in nowise substantially militates against the claims of the Englishman, William Lee, who, we think, there can be no reason to doubt, was the actual and original inventor.

The great ingenuity displayed in the invention of this excellent machine has induced us to enter at considerable length into its original discovery, which we could do with the greater propriety, as it seems to have undergone but trifling alteration for nearly 170 years, when the first important improvement was made by Jedediah Strutt, who, in 1759, obtained his Patent for the Derby ribs. From this epoch the most extraordinary efforts were made to vary and add to the mechanism of the stocking frame, so as to adapt it to the production of fancy work and imitations of pillow lace. These were at first very imperfect, but led, in the course of the next half century, to the invention of the point-net, pin-net, warp-net, and finally to the bobbin-net machines. About 1776, Horton patented his knotted frame, and soon after this the twilled and elastic machinery was invented. We shall here consider the history of the stocking frame as complete, and endeavour to give to the reader the best idea we can of its mechanism, availing ourselves in this respect of the descriptions by Mr. J. Duncan and Mr. Farey; and for the statistics of the trade we are indebted to an excellent article on the subject by W. Felkin, Esq.

(1047.) *Description of the stocking frame.*—The nature of this machine, and its operation, will be best described by first referring to fig. 1, plate lxxvii., which represents a single thread formed into a number of loops or waves by arranging it over a number of parallel needles, as shown at R, R; these are retained, or kept in the form of loops or waves, by being drawn or looped through similar loops formed by the thread of the preceding course of the work S. The fabric thus formed by the union of a number of loops is easily unravelled, because the stability of the whole piece depends upon the ultimate fastening of the first end of the thread; and if this is undone, the loops formed by that end will open and release the subsequent loops one at a time till the whole is unravelled and drawn out into the single thread from which it was made. In the same way if the thread of a stocking piece fails or breaks in any part, or a stitch drops, as it is called, it immediately produces a hole, the extension

Processes.

Description
of the
stocking
frame
or loom.
Pl. lxxvii.
Fig. 1.

Manufac-
tures.

of which can only be prevented by fastening the end. It should be observed that the stitch we have endeavoured to represent is the common plain stitch; there are several others, but the above is the foundation of them all.

Fig. 2, 3.

The wires represented in fig. 1 are what are called the needles; they are made of iron wire of the shape represented in fig. 2, 3, being hooked or barbed at the end, and the returned ends made very fine and delicate. Under the return there is a small cavity or groove punched or sunk in the stem, as seen in fig. 3, of sufficient depth to receive the point of the needle when an adequate pressure is applied upon the hook to bend the barb down. This thus becomes a closed eye, and if a thread is looped over the wire or stem of the needle, and drawn forward while the barb is thus closed, it will draw over the barb of the needle and come off at the end of it; but if the thread is drawn forward while the barb is open, it will be drawn under the hook and be thus detained, as shown in fig. 1. This circumstance must be particularly attended to, as the principal action of the machine depends upon it. The depression of the barb of the needle is produced by the edge of a presser bar, which is extended horizontally over the whole length of the needles, and is acted upon by pressing the foot on the middle treadle of the machine.

Fig. 4, 5.

Such being the form of the needles, they are now to be fitted to the frame, in order to which they are cast into tin sockets or *leads*, as they are called, which is done by placing the needles in an iron mould, which opens and shuts by means of a joint, and pouring in tin while it is in a state of fusion. The form of the needle, when complete and fitted to its place in the frame, is represented at fig. 4, which is a profile section of the needle bar exhibiting one needle. In this figure F represents a section of the presser bar above mentioned, G is the needle, and H a section of the needle bar, on the front part of which is a small piece of iron called the verge, to regulate the position of the needles. When placed upon the bar resting against the verge, another plate of iron, generally lined with soft leather, is screwed down upon the sockets or leads in order to keep them all fast. This plate and the screw are shown at I. When the presser bar is forced down upon the barb, the needle, as before stated, is shut, and when the presser rises the barb rises or opens by its own elasticity. The needles or hooks, being all properly fitted, the next part of the machine which requires description is that for forming the loops. This consists of two parts. The first of these, which sinks between every second or alternate needle, is represented at O, fig. 5, which is a transverse section of the frame, and is one of the most important parts of the whole machine. It consists of two moving parts called *jacks*, being a succession of horizontal levers moving upon a common centre, one only of which can be represented in fig. 5; but their action is seen more distinctly from the perspective view, fig. 6, on an enlarged scale. The jack shown in fig. 5 extends horizontally from O to I, the centre of motion being at R. On the front or right-hand part of the jack at O is a joint suspending a very thin plate of polished iron, termed a *sinker*, and one of these jacks and sinkers is allotted to every alternate needle in the frame; these also will be best seen in fig. 6. The other ends of the jack, seen in fig. 5, 6, are tapered to a point, and when the jacks are in their horizontal position, they are secured by small iron springs *k k*, fig. 6, each spring having a small obtuse-angled notch to receive the point of the jack, against which it presses by its own elasticity. The standards

Mechanical
Processes.

upon which the jacks move are called combs, and consist of pieces of flat smooth brass parallel to and equidistant from each other. The cross bar, which contains the whole, is of iron with a perpendicular edge or rim on each side leaving a space to receive the bottom part of the comb; these are then fixed in the bar with a flat piece of brass, called a counter comb, between each, to fix and preserve their distance from each other; the counter combs are exactly the same shape as the combs, but have no tails. When both are placed in the bar it is luted with clay so as to form a mould, into which melted tin is poured, and the counter combs being removed, the combs remain at exactly equal distances and are united with the jacks by a common axis passing through holes in each, as seen in fig. 6.

Fig. 6, 7, 8.

We have now to describe what are called the *lead* sinkers, those above spoken of being called *jack* sinkers, from their being attached to the movable levers or jacks; the lead sinkers are exactly like the former, but are differently attached, being all fixed to one bar, called the sinker bar, marked P in fig. 7. These are placed alternately between the jack sinkers, and between each sinker throughout is one needle.

We have already explained the action of the small spring which supports the jacks in their horizontal position, and by referring to fig. 6 it will be seen that when the jack sinker is elevated, so that its nip *f* is above the level of the needle ready to receive the thread, the end of the tail is received in the notch of the spring *k*, which retains it in that position; but at the same time a small force applied beneath the tail of the jack to lift it up will depress the nip *f* of the jack sinker between the needles. It will be seen that the office of the sinkers is to form the loops shown in fig. 1, but it is obvious these could not be all formed at once without danger of destroying the thread by the friction to which it would be exposed; and the means of avoiding this evil is by a very ingenious contrivance which we must next explain. A straight iron bar *l*, fig. 6 and 8, called the slur bar, is extended beneath all the jacks, and upon this a piece of metal *m*, called the slur, travels with rollers to reduce the friction; it is drawn by a line extended on each side, and conducted over a pulley at each end of the bar *l* to be carried round the slur wheel *L*, fig. 5. An alternate motion is given to this wheel by means of treadles worked by the weaver; and by this means the slur is made to travel backwards and forwards, thus depressing only one loop at a time, but in very rapid succession, and the jacks will be retained in the position given to them by the spring *k*. When all the jack sinkers are thus depressed, a loop of thread will be formed between every other pair of needles. The workman then depresses the lead sinkers, and their nips carry down the thread between the remaining needles in loops all at the same time, so that there is now a loop between every needle in the frame, the jack sinkers being made to rise up as much as the lead sinkers are depressed, making thus all the loops throughout of the same size, the jack sinkers in the first instance forming them of double the depth required.

These loops are now to be carried backward upon the needles represented at S, fig. 1, so as to come below the arch or openings of the sinkers, fig. 6, which open part is on purpose to admit the loops last made upon the stems of the needles, quite detached from the action of the sinkers, by which, therefore, may be made a new course of loops independent of the former. It remains

Manufac-
tures.

now to show how the loops are put back upon the needles. This is done by lifting up the hand bar till the points of the sinkers rise above the needles; the bar is then drawn forwards to advance the sinkers till the thread is behind the points *t*, then depressing these and pushing back the hand bar, the points *t* carry back the loop upon the stem of the needle, as above stated, under the arch of the sinker. The first row of loops being thus disposed of, the frame of sinkers is restored to its original position, and a second row of loops is formed on the stem of the needles by a repetition of the same process; and this row is now to be brought forward so as to be under the barbs or hooks of the needles, which is done by drawing the hand bar forwards till the thread is in its required place beneath the hook. By the action of the treadle the presser bar is made to act upon the barbs of the needles to close them with the thread within them. The first formed loops are now brought forward upon the closed needles, and thus pass over the end of the needle, and the new formed loop within them. By this means the loops of what was the upper or last course of the finished work become secure from unravelling, and the loops under the barb now become the upper course, and are made to occupy the place of the former, and thus, in succession, the several rows are rendered one entire piece. The loops *S, S*, fig. 1, represent only a single line of loops; the reader, however, must consider them as the upper row of the work done in proper connection with it.

We are afraid the above description will give but an imperfect idea of the operation of this exceedingly ingenious piece of mechanism; but to have rendered it more intelligible, or, at least, so much so as to have illustrated its entire action, would have occupied more space and more figures than we could bestow upon it in a Treatise of this kind which embraces so many different processes and machines. We trust, however, that a tolerably general idea of its operation may be acquired from what has been stated. The description we have attempted relates only to the plainest work; a different combination is required for ribbed, plated, and fancy work, which, with the exception of the ribbed stocking frame, we must pass over, for the reasons above stated.

Ribbed
stocking
frame.
Fig. 9, 10.

(1048.) *Ribbed stocking frame*.—The frame which, next to the common frame, is most extensively in use, is that employed for working stripes or ribbed stockings. In principle it does not differ from the common frame, and not greatly in construction; the foregoing general description will apply therefore equally as well to this as to the former; that part, however, by which the ribs or stripes are formed is entirely an addition, and to the application of it, it may be proper to pay the chief attention. See fig. 10, which is a profile elevation. The principle of weaving ribbed hosiery resembles considerably the weaving of that kind of cloth called tweeling, for the formation of stripes, with some variations arising merely from the different nature of the fabric. In cloth weaving, two different kinds of yarn, intersecting each other at right angles, are employed; in hosiery only one is used: in the tweeling of cloth, such as dimity, cotton, kerseymere, or woollen manufactures, the stripes are produced by reversing the yarns; in hosiery, where only one yarn is required, a similar effect takes place by reversing the loops; but in order to give this effect, a second set of needles is placed upon a vertical frame so that the bends

of the hooks may be nearly under those of the common needles. The needles are cast in tin moulds, as in the common machine before described, but more oblique, or bevelled towards the points to prevent any obstruction in their working; they are also screwed to a bar of iron, generally lighter than the other, and secured by means of plates; this bar is not fixed, but has a pivot in each end, by means of which it has free motion on the pivots. Two frames of iron support the bar; that in which it oscillates being nearly vertical, but inclining towards the other needles. Fig. 10, which is a profile elevation, will serve to illustrate the relative position of one bar to the other, the lower or horizontal frame, the ends only of which can be seen in fig. 9, under *aa*; these are shown in profile, fig. 10, marked *d*; the vertical frame at *a* is attached to this by two centre screws, which serve as joints for it to move in. On the top of this frame is the ribbed needle bar at *f*, in fig. 10; one needle is also represented in fig. 10 at *f*; *g* is a small presser to shut the barbs of the rib needles, in the same manner as the large one does those of the frame; *h* is one of the frame needles, to show the relative position of the one set to the other; the rib bar is not filled with needles, since it will be seen they are only required where ribs or stripes are to be formed, the intervals being filled up with blank leads, that is to say, the sockets are the same shape as the others but without needles, being merely designed to fill the bar and preserve the spaces. Two small handles are suspended from the needle bar by which the oscillatory motion upon the centre is given; the up-and-down action is communicated to this machine by chains, which are attached to iron sliders below, and which are wrought by the hosier's heel when necessary; the pressure takes place partly by the action of the smaller presser, and partly by the motion of the needles in descending; there is also a small iron slider placed behind the rib needles, which rise as they descend and serve to free the loops perfectly from each other.

In the weaving of ribbed hosiery, the plain rib courses are wrought alternately; when the plain is finished, the rib needles are raised between the others, but no additional yarn is required; the rib needles, intersecting the plain ones, merely take up the last thread, and, by again bringing it through that which was on the rib needle before, give it an additional looping, which reverses the line of chaining, and raises the rib above the plain intervals, which have only received a single knitting.

In concluding this article, the following statistic statement of the hosiery trade in 1833, we have no doubt, will be interesting to the reader.

(1049.) Worsteds hosiery is chiefly made in Leicester-shire; silk hosiery in Derby and Nottingham; and cotton hosiery throughout the Counties of Nottingham and Derby, at Hinckley, and at Tewkesbury. The analysis furnished by Blackner, in 1812, may be perhaps modified as follows, so as to show the kinds and qualities of goods which the frames were, in 1833, employed upon, *viz.*:

Plain cotton, 14 to 22 gauge, 1600; 24 to 28 gauge, 1600; 30 to 34 gauge, 2790; 36 to 60 gauge, 1600 frames	7,590
Gauge, 600; gloves and caps, 1000; drawers, 500; sundries, 560	2,660
Wide frames, making cut-ups and various other kinds	6,030
Carried forward	16,280

Mechanical
Processes.

Statistical
statement
of the
hosiery
trade.

Manufac-
tures.

	Brought forward	16,280
Worsted 12 to 20 gauge, 4400; 22 to 26 gauge, 3600; 28 to 34 gauge, 1450 frames		9,450
Angola, 1350; lamb's wool, 1900; shirts, 500 frames		3,750
Wide frames with worsted goods		520
Silk, 2300; gloves, 350; and knots, 350		3,000
Total of frames		33,000

The following statement, it is believed, presents a sufficiently accurate approximation to the annual amount in quantity and value of goods manufactured in this trade to answer all practical purposes. Each narrow cotton frame produces about 40 dozen of hose a-year, if of women's size; wide cotton frames 300; narrow worsted 75; wide worsted 150; and silk 30. There are

10,300 frames making fashionable cotton hose which produce 420,000 dozens, and consume 880,000 pounds of cotton yarn valued at £73,000, wages for making which £220,000, and finishing £32,000, total £325,000.

6000 frames making cut-ups, &c., produce 1,960,000 dozens, and consume 2,940,000 pounds of cotton yarn valued at £172,000, wages for making which £285,000, and finishing £98,000, total £555,000.

9500 frames making fashionable worsted produce 710,000 dozens, and consume 2,840,000 pounds of worsted valued at £284,000, wages for making which £215,000, and finishing £41,000, total £540,000.

1000 frames making cut-ups, &c., produce 100,000 dozens, and consume 400,000 pounds of worsted valued at £40,000, wages for making which £30,000, and finishing £10,000, total £80,000.

1300 frames making angola produce 95,000 dozens, and consume 332,500 pounds of worsted valued at £45,000, wages for making which £40,000, and finishing £19,000, total £104,000.

1900 frames making lamb's wool produce 135,000 dozens, and consume 639,500 pounds of worsted valued at £80,000, wages for making which £50,000, and finishing £16,000, total £146,000.

3000 frames making silk produce 90,000 dozens, and consume 105,000 pounds of silk valued at £120,000, wages for making which £108,000, and finishing £13,000, total £241,000.

Total 33,000 frames, which produce 3,510,000 dozens, using 8,137,000 pounds of materials of £814,000 value, to which add wages £948,000, and finishing £229,000, total £1,991,000.

According to this calculation, the value of the cotton hosiery annually made is £880,000; that of worsted, &c. is £870,000; and that of silk is £241,000. To produce these goods it is probable that 4,584,000 pounds of raw cotton wool, value £153,000, are used, and 140,000 pounds of raw silk, (two-fifths China and three-fifths Novi), value £91,000, also 6,318,000 pounds of English wool, value £316,000. The total original value of the materials used is, therefore, £560,000, which, it appears, become of the ultimate cost value of £1,991,000 in this manufacture. There are employed in the various processes as follows, viz.,

In cotton spinning, doubling, &c.	3000 persons;	
worsted carding, spinning, &c.	2500;	
silk winding, throwing, &c.	1000	6,500
In making stockings	13,000 men, 10,000 women, 10,000 youths; women and children in seaming and winding, &c.	27,000
		60,000

Carried forward 66,500

Brought forward	66,500
In embroidering, mending, bleaching, dyeing, dressing, putting up, &c. probably about . . .	6,500
Total persons employed	73,000

Mechanical
Processes.

The capital employed in the various branches of the trade may be thus estimated, taking the machinery and frame at neither their original cost nor actual selling price, but at their working value, and the stocks of hosiery on an average of years.

	£.
The capital in mills and machinery for preparing cotton is	70,000
Ditto worsted, &c.	52,000
Ditto silk	18,000
Fixed capital in mills, &c.	140,000
Ditto in frames	245,000
Total of fixed capital	£385,000
In wool and yarn in process and stock . . .	85,000
Ditto worsted, &c.	150,000
Ditto silk	35,000
Floating capital in spinning, &c.	£270,000
Capital in narrow cotton frames	62,000
Ditto wide	60,000
Ditto in narrow worsted frames	76,000
Ditto in wide	11,000
Ditto in silk frames	36,000
Fixed capital in frames	£245,000
In goods in process and stock	350,000
Ditto	345,000
Ditto	85,000
Floating capital in making hose	780,000
Ditto in spinning, &c.	270,000
Total of floating capital . . .	£1,050,000

The number of frames in each locality has very materially varied since 1812. Many have been widened to make two stockings at once, and about 5000 wide frames are making cut-up work. The quantity of cotton goods made now is probably more than half as large again as at that time. Then there were about 100 hosiers at Nottingham, now there are but about 40. The number in Derby has varied little; but in Leicester it has increased. One house employs upwards of 3000 frames; a second about 2000; a third and fourth about 1800 each; a fifth 1500; and other various smaller numbers. Many of these are their own property, and an annual rent of about 40s. coarse, 50s. fine, 75s. silk, and 100s. wide frames, is paid for each by the workmen. This rent has always been considered an important source of income to the hosiers, and an important deduction by the hands: at present it amounts to about one-sixth of their earnings, and is, in fact, a payment of one per cent. weekly of the full market value of the machine. Many thousand of narrow frames have been bought at £4 or £6 a-piece, but probably all of them needed repairs, and every six or seven years further reparation, to a greater or less amount, will be needed. Some hands will wear down a frame in three years; others, however, will work them twelve or even twenty years without serious repairs, or, as it is technically called, a recruit. Each six years' recruit may cost £5; and thus 1000 frames, bought at £5 each, would

Manufac-
tures.

cost in original outlay £5000, and first recruit £5000 ; and as he would receive £15,000 in rent, if owned and employed by a hosier, he would clear £5000, or about £800 a-year ; and the next and each succeeding six years the expense would be the recruit only, and of course the amount of annual profit about £1600. Against this there is to be placed, however, the serious inconvenience and loss often sustained by the hosiers from depreciated or dead stock, created in employing these machines through flat periods, when otherwise they might be standing still. It has been seen that the frames are gradually accumulating in the hands of large manufacturers.

It is supposed that one-half of the full-wrought, and three-fourths of the cut-up, work passes from the work-people to the hosiers (it is almost entirely a domestic manufacture) through the hands of the bag-hosiers ; and as it seems quite impossible to get these men to pay entirely in money, this circumstance is felt by the hands to be a great and increasing evil ; in fact, the truck system exists in some places to a considerable extent. Wages have fallen in each branch of the framework knitting trade, during the last thirty years, about thirty per cent. The present net earnings of the worsted hands may be taken at 3s. to 6s. a-week ; of the cotton hands 4s. to 7s. a-week ; of the silk hands 6s. to 12s. a-week. Workmen making cut-up goods earn from 10s. to 21s. a-week. As this includes the youths and women employed in the frames, it is certain that, although many hands working fine gauges, or employed upon particular makes of goods, will gain more than the highest sums stated, a far greater number receive less than the lowest, which is the earnings of the great bulk of the workmen. In some periods of almost total stagnation in this trade, and when in many of those parishes which are inhabited chiefly by framework knitters the rates were becoming so large as to alarm the overseers of the poor, some of these officers bought cotton or worsted and employed stocking-makers who were without work instead of otherwise relieving them. By this plan temporary benefit occurred to the parishes and to the trade ; in one or two instances the goods were held over to a favourable season and realized somewhere about cost price ; but in the generality of cases they were sold at a great loss to the parishes or individuals who engaged in the speculation, and with much detriment to the trade, sales being most probably effected after long-continued depression. And thus, combined with the revulsion upon the supply of labour in the market by the return of the hands so employed, these sales operated to force wages and the value of stocks on hand lower than they otherwise might have been brought. These experiments shared the fate of the majority of irregular and unnatural interferences with the relation between the money and labour capital employed in any trade.

The consequence of the before described long and extreme depreciation in the value of the stocking-maker's labour are very apparent and deeply to be lamented. Most of their employers regret that which appears to them an inevitable result of the existing weight of public burdens, (bearing, as they think, peculiarly heavy upon manufacturers,) and of the surplus labour competing for employment in this as in most other manufacturing districts, and but few amongst them seem to expect any material improvement either in demand or wages. The workmen, speaking of them in the mass, are physically deteriorated ; they are mentally depressed, and too often

mechanically debased ; ill-fed, ill-lodged, and ill-clothed, with care-worn and anxious countenances, they are a class by themselves, and easily distinguishable from most others by their personal appearance ; and without attributing their extreme poverty to them as a crime, which is but their misfortune, we shall, nevertheless, be prepared to learn, what is indeed the fact, that amongst them, as amongst others similarly circumstanced, hopeless poverty is producing fearful demoralization, of all others the most certain effect of wages depressed too low, and the result most to be deplored, because the most difficult to cure.

It is supposed that during that period the hosiers' profits have decreased in an equal, if not greater, ratio than the depreciation of wages paid to those whom they employ. The respective amounts of the business done by the larger houses is of course much increased, while their numbers are materially diminished. A remarkable change has also gradually occurred during the last fifteen or twenty years. Formerly London was considered the chief hosiery mart, and a comparatively small portion of the goods was sold in Nottingham, Derby, or Leicester, most of the hosiers having houses for the sale of their goods in the metropolis : now the business is almost entirely transacted at the manufactories, or by consignments from thence abroad. Nottingham is, therefore, become the centre of the cotton hosiery trade, Derby and Leicester for the silk and worsted hosiery business respectively. The greater part of hosiery goods is yet sold for home consumption ; large quantities are, nevertheless, exported of low fashioned articles to New York, Philadelphia, New Orleans, Buenos Ayres, Lima, Rio, Lisbon, and other places ; to the West Indies and Bengal of fine cotton and silk hose ; and the export of cut-up goods has much increased of late years. As, by a recent improvement in the manner of making many of this kind of goods, more fashion is obtained with little more cost in labour, (three frames are employed upon this plan in making each stocking,) it is probable that a further enlargement of the foreign hosiery trade may, ere long, take place.

The number of hosiery frames throughout the Continent, &c. was thus stated by Blackner, in 1812, viz.,

In Paris 1000 ; Lyons 1800 ; and in twenty-two other towns in France 3955	6,855
Netherlands 520 ; Spain and Portugal 1955 ; Italy 985 ; Germany 2340 ; Petersburg, &c. 200 ; Stockholm 30 ; Copenhagen 35 ; North America 260	6,325

Total number of frames abroad 13,180

It is very probable that the number of these machines is considerably larger now than is stated above, especially in Germany, where many coarse worsted and cotton hose are made both for home consumption and exportation. Some have found their way to this Country at different times, where they are sold in bond, chiefly for America. French silk stockings are very extensively made, of good workmanship, and at a cheap rate, in the districts of Nismes, Andune, Aix, Avignon, &c., and have somewhat the preference to ours in several foreign markets. These circumstances furnish the hosiers with powerful arguments against any forced rise in wages here, however depressed they may appear. The wages of the German framework knitters are very trifling, but their cheap provisions enable them to live in tolerable comfort. Good wages are paid in Paris, and they are not low for stocking-making throughout France. Most

Mechanical
Processes.

Manufac-
tures.

of these foreign frames are very old and their insides are generally in very bad repair. The carcasses are in many cases, as indeed not a few are in England, from 100 to 150 years old. While the hosiery cotton yarn used in this Country is often of a single stand, and now rarely of more than two stands, which, when the yarn is well spun from good wool, is all that is necessary to ensure sufficient strength, yarn of five or six stands is commonly employed abroad, the stands being very unevenly spun from inferior wool. To produce good hosiery yarn is found by the English cotton spinners one of the most difficult parts of the business. As most of the foreign cotton hose are made of the coarser qualities, smuggled fine English stockings have long been more estimated and fashionable in Paris than the best silk hose. Were our thirty-six gauge or sixty-gauge cotton stockings permitted free introduction into France, the demand for them in that market would be immense. As our commercial intercourse and interchange of commodities and manufactures with France is now progressing, the manufacturers of Nottingham and their poor workmen might possibly be well repaid for any efforts they might expend in the pursuit of freedom of trade between the two Countries in this as well as other articles.

Manufac-
ture of fish-
ing-nets.
Pl. lxxvi.
Fig. 5, 6,
7, &c.

(1050.) *Fishing-nets*.—The making of fishing-nets may, at first sight, appear a very limited branch of manufacture, scarcely calling for our notice; but when again we look at the present and increasing importance of the British fisheries, it will be found that an expeditious and cheap method of manufacturing such articles is by no means an object of indifference. Several inventions of this kind exist: one was rewarded by the Society of Arts so early as the year 1796; another was proposed and rewarded by the same Society with a purse of fifty guineas in 1808; others have been invented by Mr. J. Duncan, the author of a Work on weaving, and of various articles in the *Edinburgh Encyclopædia*; but of these we can only describe one, and we consider that by Mr. John Robinson, of Edinburgh, which is the one alluded to above as having received the reward of fifty guineas, to be very simple, and best suited to give the reader a general idea of the operation. In plate lxxvi. we have given a representation of this machine, fig. 5 exhibiting it in a state ready to begin working, supported in a wooden frame. A is a beam on which the twines for the net are rolled, in number equal to the knots tied, and from which they pass through circular tubes fixed in a bar B, (shown by dotted lines through the pulley, seen better in fig. 6,) which is fixed near the circumference of two equal pulleys C, C, that turn on their axes by means of a cross treadle, with small pulleys at each end D, D, through which passes a band, one end of which is fastened on the frame at E, and the other on the pulley C. At F the band through the other pulley has one end fastened on the frame G, and, being wound round the furthest pulley C, is fastened on the under side of it, which, by the alternate action of the treadle on its axis H, moves the pulleys C, C, and circular tubes, from their situation in fig. 5 to that in fig. 7, and back again. In the centre of the pulleys C, C is fixed another bar P, with a dovetail groove, where the pirns that contain the twine are supported, (it being necessary to have two threads for every mesh, also one pirn more than there are tubes.) In a groove under the dovetail is a slider L, moved by a wire K, fixed in each end of it, having pins in it, by which it moves the pirns backwards or forwards over the notches in the bar I, so as to cast a part of the knot;

the pulleys C, C and bar B move round the bar I, as an axis, but independent of it, the bar being fastened through the pulleys to the frame; M is a movable bar (centred within two supports N, N, having two joints) with hooks, both for catching the twine at the end of the circular tubes, and, by crossing the hooks to the other side of the points of the tubes, to give the twine a turn of forming the knot, and, by raising the points of the hooks, the ends of the tubes enter between them, as shown fig. 8; and by the circular motion of the bar B, when the two pulleys C, C are turning on their centres by the foot on the end, No. 1, of the cross treadle, and until the knots so formed are close to the bar B, fig. 7, (it is then what is called a running knot,) a part of which falls into a notch cut below the level of the supporters of the pirns in the bar I; then slide the pirns over the notches that contain the twine; the knot is then cast, and then by the foot on the other end, No. 2, of the cross treadle, until the points of the tubes are returned to their former position; then remove the knot by disengaging the hooks and the tubes; then the knots are made tight as the wrought part of the net is rolled on the beam O, on one end of which there is a pulley P, with a band that communicates with the pulley on the end of a short roller Q, in which are fixed four cross bits of wood that answer the purpose of treadles for the feet, by which it is drawn tight; R is another short roller communicating with the roller A, serving to give out the proper quantity of twine for the length of the meshes, or to hold it while the other roller tightens the knot; S is the seat. Fig. 6 is a plan of the machine, the movable bar and treadles left out to prevent confusion. Fig. 7 is the situation of the running knot when the pirn goes through it.

Fig. 9 is the tube in the same position, showing the manner the knot is twisted round it, and having the pirn and slider L taken out of the bar I, the dotted lines showing at what height they come together; in the slider L there are two pins, T, T, to prevent its rising high enough to touch the string, and in the bar I there are two wires O, O, like staples, to support the slider L in its place. Fig. 10 is the movable bar M with the hook. Fig. 11 shows the hooks at large. Fig. 12 is the bar I, showing the notches in which the strings lay to let the pirns pass over them, (when the tubes are brought over as in fig. 7.) Fig. 13 is the slider L, with the pins that move the pirns.—*Trans. Soc. Arts*, vol. xxiv.

Tambour work.

(1051.) *Tambour work by machinery*.—Although this Tambour work can hardly be considered as forming a great branch of British manufacture, yet the number of hands formerly employed upon it was much more considerable than one would have been led to suppose. It is estimated that, before the invention of the tambouring machine, as many as twenty thousand girls and women were employed on this work in the vicinity of Glasgow only, gaining, however, but a very scanty and precarious livelihood. This part of the subject, viz., the actual needlework by hand, it is not our intention to touch upon in this place; it is sufficient to say that, by passing the needle backwards and forwards in particular directions, flowers, birds, and other ornamental work were produced. We propose only to describe the manner in which this is now performed by machinery. The invention of the tambouring machine is due to Mr. J. Duncan, of Glasgow, who has given an interesting

Manufactures.

description of the machines, and the way in which he was led to undertake its construction, under the term of chainwork, in Brewster's *Encyclopædia*, which we propose to avail ourselves of in the present article.

Mr. Duncan states that the first idea of this machine arose from a casual conversation with a gentleman, at that period extensively engaged in the muslin manufacture, and fond of mechanical pursuits. Some study convinced the inventor that the construction of a machine which, by bringing into action a great number of needles at the same time, would shorten the process by manual labour, and might be rendered actually efficient, was perfectly practicable. The diversification of pattern seemed to constitute the whole difficulty, and the application of the composition of forces, acting at right angles to each other, presented a facility of overcoming this obstacle, which encouraged him to proceed. To apply this principle in the various ways which might effect this purpose, did not occur for a long time afterwards, and his first idea was confined to the construction of a machine which might be put in motion by a person who should exercise his discretion in shaping the pattern, whilst he should be enabled to perform all the other operations by the pressure of his feet. It seems more easy to move the cloth than the needles, and for this reason the cloth frame was made to move in both directions; at the same time he received a suggestion that a perpendicular position might admit of many conveniences of which a horizontal one could not be made susceptible, and adopted it. After some consideration, a machine was constructed under his direction, and afterwards a second, which he only occasionally superintended, being at that time engaged in other pursuits. After two years, he formed a connection by which his whole study and time were to be devoted to the completion and practical application of his invention. Six of the machines were set to work in this way; after which he was sent to London by the Company, in order to procure the Patent, and comply with the necessary proviso, which requires a specification of the invention to be enrolled in the Court of Chancery within thirty days of the sealing of the Patent. At this period, the idea of rendering the machine automatic had barely presented itself to him, and, consequently, the last part of the specification only described the possibility of applying such mechanical power. Upon his return, he extended and applied this principle so long as the work was under his direction. The results of that experience, and what afterwards occurred to him, are found in the description which follows.

Pl. lxxiv.
Fig. 1.

Plate lxxiv. fig. 1, is a transverse elevation, viewed in front, or at that part where the person who has the care and superintendence of it is supposed to be placed. At A, A, A, are three upright posts, being exactly one half of what are used, those behind corresponding in every respect with those in front. At B is a horizontal cross rail, of which one is before and two behind. The frame in which the cloth is stretched appears at C, the lower beam and under part being concealed by the beam D, but correspond in every particular with the upper part, which is visible. C is the middle frame, which in that work contains fifty-four needles, each being placed at the distance of one inch asunder, and designed to tambour a piece of muslin six-fourths wide, one whole row being wrought at the same time. The cloth frame is suspended so that it will move freely, and without the exertion of much power, either upwards

or downwards, and with equal facility from right to left, and *vice versa*. To ensure this, the roller G is placed above; and in order that both sides of the cloth frame may rise and sink equally, cords are attached to each end, which, after passing a sufficient number of times round the roller G, descend upon the opposite side, where the weight of the frame is nearly, but not quite, counterpoised by the weights L, L.

The tension of the cloth is preserved by ratchet wheels and catches to either roller, precisely as in a common tambouring tent; and in order that it may be stretched *laterally* as well as *vertically*, at each side is a piece of iron filled with wire hooks which take hold of the selvage of the cloth, as used at bleach-fields, and called by the name of tenters. In the doubling framing at the right hand, that part of the machinery which forms the pattern is contained, and this consists of four wheels fixed upon the same axis, which is a bar of iron one inch square. Of these wheels, three are eighteen inches in diameter, and one twenty-six inches. The wheel nearest to the front of the machine is a ratchet, and merely regulates the motion of the others. It is customary to form two flowers by one revolution of the axis, because when the flowers are similar every second row is reversed, and when dissimilar, every alternate row is of the same form. In the first case, the ratchet wheel forms a flower by half a revolution; in the second, the number of teeth correspond to the number of loops or stitches in the respective flowers; the next wheel in order is to communicate the horizontal motion to the frame in which the cloth is suspended; the third wheel gives the perpendicular motion; and the fourth, or twenty-sixth inch wheel gives a rotary motion to the needles upon their whole axis. The second and third wheels, of course, are those immediately employed in the formation of patterns; and it may be proper in this place to give some account of the principle by which they are fitted for this purpose, as it is by far the most curious and least understood part.

To apply this principle to the construction of the tambour machine, or to any other requiring extensive varied motion, it was only necessary to produce two direct motions, which, as being the most simple and efficient mode of construction, were placed at right angles to each other, one being in a vertical and the other in a horizontal direction; and as it is easier to communicate motion to one body than to many, it was found better that the motions which produce a relative change of position between the cloth and needles, so as to regulate the successive points of perforation, should be given to the former rather than to the latter. In the first construction of the machine, the motion given the cloth frame was effected by two screws, one placed vertically and the other horizontally. As the machine in this state was wrought by the operator's hands and feet, and entirely under the guidance of his discretion, the screws were turned by his hands by two small winches, so calculated that, when either winch was turned to the extent of a quarter of a quadrant of one revolution, a shift of the cloth equal to one-thirty-second part of an inch was produced. This was found a proper length when the motion was directly given by one screw, either vertically or horizontally. But when any immediate angle was to be formed, it required that the shift should be less in both screws, as the oblique line produced by the combining action of both screws was always greater than either side apart, in the same ratio that the hypo-

Mechanical Processes.

Manufac-
tures.

then use of a right-angled triangle exceeds that of either of the sides. When the screws were judiciously turned, this operation succeeded very well; but as the ratio of the one to the other constantly varied, even the most careful operators, totally ignorant of the simplest elementary principles of trigonometry, were in constant danger of errors; and when intrusted to women or boys, which consideration of economy rendered peculiarly desirable, it was found impossible to place much reliance upon the quality and regularity of the work. These reasons, therefore, induced the inventor seriously to endeavour to find some remedy, which, by fixing the motions of the machine under regular mechanical laws, should entirely remove both the blunders and inaccuracies of human agency; and this he was enabled to effect by removing the screws and substituting the traverse wheels. When this point was gained, very little more was necessary to render the machine entirely automatic, and this was speedily effected.

The cloth frame being loosely suspended, and its motion regulated by the cylinder above, it was further suspended by the centre from one end of the lever H, the other end of which was connected, by means of two stout iron wires, with a piece of iron furnished with a small friction wheel, and acting on the rim of the perpendicular traverse wheel directly under its centre. The tendency of the frame to descend produced a gentle pressure of the friction wheel against the rim of the traverse, and according to its shape the frame was either lowered or raised at every shift of the wheel.

The communication between the cloth frame and the horizontal traverse was effected merely by a small connecting bar of iron between the edge of the cloth frame and the wheel, the rod being placed directly level with the centre of the wheel. The pressure against the wheel was very simply effected merely by tying a piece of whipcord to the frame, and, after passing it over a pulley, suspending by it a small weight to its other extremity. A screw was also attached to the breast beam, by which the cloth frame could be raised at pleasure, to present fresh cloth by shifting a notch in the suspensory rod C. Thus ten or twelve rows could be wrought without shifting the beams upon which the cloth was stretched. The general motion was communicated by a leather belt passing over the pulley at N, and the machine could be engaged or disengaged at pleasure, by means very similar to those used for other machinery. When a flower was finished, the ratchet wheel moved a small lever, which instantly stopped the machine in order to prevent accidents. There were three treadles below, moved by wipers upon the cross shaft, by which all the motions were given. The first plate served to set forward the needle frame, so as to produce the perforation of the cloth by the needles; the second, P, set in motion that part of the machinery which supplies the needles with thread, and the third, P, moved the ratchet wheel one tooth between every perforation.

Rope-making.

Common
process
of rope-
making.

(1052.) Rope-making is an Art of unknown origin, and is, with great probability, supposed to be of very ancient date. The fibres commonly employed for the purpose are hemp or flax, but attempts have been made to employ wool and some other materials. The first part of the process of rope-making is that of spinning the yarn or threads, which was formerly, and is at

present, frequently done by men having a quantity of hemp or tow fixed about their waist, and walking backward in long rope-grounds, the thread being twisted by an attendant, or by some first mover at the end of the ground or walk. The sliver of hemp being placed round the waist so that the two ends come in front, the workman draws out a proper number of fibres with his hand, twists them with his fingers, and fixes this twisted part to a hook of a whirl which is driven by a wheel, put in motion as above described; he then walks backwards, supplying the hemp as required, hanging it as he proceeds on hooks fixed for the purpose. As soon as he reaches the end of the walk, another spinner takes the yarn off the whirl and gives it to another person to put on a reel, and then, attaching his own hemp to the whirl, walks in like manner down the ground.

Mechanical
Processes.

The next part of the process is that of stretching the yarns, so as to make them all of the same length, which is called warping; the next is that of tarring the yarn; and the last is that of laying the cordage.

In this, two or more yarns are attached at one end to a hook; this is then turned the contrary way from the twist of the yarn, and thus is formed what is called a strand. Three strands, and sometimes four, besides a central one, are then stretched at length, and attached at one end to contiguous but separate hooks, and at the other to one single hook; and the process of their conjoint combination, which is performed by turning the single hook the contrary way to the other three, consists in regulating, by duly retarding it, the progress of the twist of the strands round their common axis, whilst at the same time the strands receive separately, at their opposite ends, just as much twist as is taken out of them by their twisting the contrary way in the process of combination.

This, in all probability, was the extent to which rope-making arrived for many Ages; as the cordage for ships, and other applications of rope, did not formerly require that size which rendered further combination necessary. The individual yarns composing a strand are limited in their thickness; because, if exceeding a given size, the fibres of hemp or other component substance have not a sufficient number of turns round their common axis to prevent their slipping when the yarn is stretched; therefore, when the rope became thick, the requisite number of yarns to form a strand was very great, and, in general, many were broken on their being twisted together in one spiral; for the outward coat of threads or yarns are necessarily exposed to more stress than the internal ones, lying at less distances from the centre of the cylinder, so that when twisted together, the outside yarns form a spiral of a number of turns round the mass of the included yarns, and are therefore much shortened; whilst the inner yarns take only the same number of turns round a reduced axis, and, from that cause, are less shortened; therefore, it follows, that the outside yarns only can be in full tension, whilst those within must be more or less coiled up according to their proximity to the centre. The result of this erroneous principle of forming strands was obvious, and probably led to the formation of great ropes, by the combination of the lesser ones round a common axis, in the same manner as a shroud-laid rope is formed by the combination of strands round their common axis; and the rope, thus formed by the combination of three shroud-laid ropes, is said to be cable-laid; as, upon this principle, cables and water

Manufac-
tures.

ropes are made, even when their magnitude does not require their strands to be inconveniently large; the object being to make the rope more hard and compact, and thus to prevent the too easy admission of water, which is of course injurious.

The short duration of ropes, exposed to be alternately wet and dry, necessarily led to the invention of some simple and cheap preservative, which, by the general practice of all nations, has been supposed to be best effected by the use of boiling tar, through which a mass of yarns, generally consisting of two to three hundred, are slowly drawn and compressed on leaving the kettle, so as to discharge the superfluous quantity.

In this state, the Art of rope-making continued to near the close of the last century, and, with a few exceptions, is still the same, notwithstanding many very ingenious machines and contrivances, which are, however, but partially employed. Mr. Chapman, in an ingenious Work on this subject, has given these in considerable detail, and we are indebted to him for the following particulars.

Rope-
making by
machinery,
Mr. Sylves-
ter's me-
thod.

(1053.) The first attempt at an improvement was made by Mr. Sylvester, who deposited a model of his machine in the repository of the Society of Arts in the Adelphi, prior to the year 1783.

The design of this machine was to supersede the necessity of a rope-ground, by enabling the process to be carried on in a house; for this purpose he spun the thread on a bobbin and spindle; and by his model, the yarns requisite to make the strands were wound on three separate reels, fixed on frames which turned individually round their axes, and also round a common centre, by which they were all three twisted together into a rope, which was to be wound up or coiled away progressively as made. The great defect of this machine was, that the process of making the strands and twisting them into a rope did not proceed at the same time; but a portion of the strands was first made, and afterwards twisted into a rope, imitating the process in a rope-ground, where the strands and rope are made in separate operations at full length.

The next invention was secured under his Majesty's Letters Patent, in 1784, to Mr. Benjamin Seymour, for a new method of making ropes. This appears to have consisted in substituting horses in the place of men to move the machinery at the head of a ropery, viz., the twisting of the strands, and all the different processes until completed in a cable.

Cart-
wright's
Patent.

In 1792, the Reverend Edmund Cartwright obtained a Patent for a machine for making ropes, which he called a cordelier.

This machine was so far similar to Mr. Sylvester's, that three separate reels, containing the yarns to compose the strands, were placed on as many frames, each turning round its individual axis, whilst the whole moved round an axis common to the three; but it differed essentially from the former, by both these motions proceeding at the same time; so that the twisting of the strands and of the rope kept pace with each other, and were therefore capable of producing the desired end, the rope being progressively drawn away as made.

Fothergill's
Patent.

In 1793, Mr. Richard Fothergill, of Sunderland, in the County of Durham, obtained a Patent for "a machine for dressing hemp, and making and spinning the same into ropes and cordage." This invention consisted in a method of heckling and preparing the hemp, and in spinning it into rope yarn; and in laying the cordage by

a machine on the principle of Mr. Cartwright's, but differing from it in its being vertical like Sylvester's, whilst the revolving shafts of Mr. Cartwright's were horizontal, and more particularly in its internal regulations. It was capable of making ropes without the necessity of a rope-ground; but, excepting so far as any advantage arose from the greater uniformity of the whole process, it went only to the reduction of labour, and concentration of it to a more limited space. It was, however, carried into effect upon a large scale, and at a great expense in buildings and machinery, at Southwick, on the river Wear; but was at first very limited as to the manufacture, until such further improvements were adopted as will be subsequently described. A perspective view of that part of this machinery for making ropes is given in plate lxxviii., fig. 1, in which *a* is the platform, by the revolution of which the three strands are twisted into ropes at *b*, their point of junction, from which it is drawn forward as made by the wheel *d*; *c, c, c* are the separate strand wheels, each containing the requisite number and length of yarns for a strand, and fixed in its respective strand frame, revolving round its own axis at the same time that they are all carried round by their supporting frame *a*. Fig. 2 is a yarn spindle and bobbin.

Mechanical
Processes.

Pl. lxxviii.
Fig. 1, 2.

(1054.) In the same year, i. e. 1793, Mr. John Daniel Balfour, of Elsinour, in the Kingdom of Denmark, obtained an English Patent for his "new invented machine for making and manufacturing ropes and cordage." We have already described the usual process of forming the strand of a rope, and shown that it must be defective; because a given number of spirals round a large cylinder must require a greater length of yarn than the same number of spirals round a small cylinder of the same length as the large one.

Balfour's
Patent.

To remedy this, Mr. Balfour's method was to stretch out at length in a rope-ground all the yarns wanted for the formation of a strand, to such length as the strand was required to be; the residue, viz., so much at least as the length of the yarns would exceed the proposed length of the strand, was to be wound up on as many individual bobbins upon a large frame as there were yarns. Those yarns were separated at intervals, throughout the whole length from the frame to their commencement, where the operation of twisting the strand was to begin. Here the yarns were all united, either through concentric circles of holes, or round the notches of an implement which he called a *top minor*. The operation then began by twisting the whole of the yarns in mass at that end, and retiring with the top minor as the twist advanced. In this case, as the yarns at the opposite end had the means of drawing off individually from their separate bobbins, they each would unwind no more than their internal or external position in the spiral required, and would, of course, be of different lengths. This plan was very ingenious, and had much merit in its principle, although defective in stopping short of what would effect the ultimate purpose of causing all the yarns to bear alike on breaking the rope. Before a rope is brought to its breaking stress, both it and the strands composing it are much elongated, and their diameters greatly reduced. Now, under any reduction of diameter of strand, it is apparent that the outside coat of yarns must slacken considerably, and give little or no support to the internal yarns, which, from the smallness of their spiral, could elongate but little, and must, of course, break in succession from the centre outwards. In addition to this defective circumstance, the mode

Manufac-
tures.

Huddart's
Patent.

of operation was so complex and laborious as to prevent its adoption.

The deficiency, in point of principle, in the above method, was remedied in a Patent taken out also 1793, by Mr. Joseph Huddart, of Islington, in the County of Middlesex, for "a new mode or art of making great cables and other cordage, so as to attain a greater degree of strength therein, by a more equal distribution of strain upon the yarns."

Mr. Huddart's formation of the strand is essentially the same process, except that he places, behind the movable implement which Mr. Balfour calls a top minor, a tube of two parts divided longitudinally, and overlapping each other, which is formed of thin steel, of spring temper, to be more or less compressed at pleasure.

The top minor of Balfour is with Mr. Huddart composed of a plate with the requisite number of holes for the yarn, placed in concentric circles; and connected with this plate, at such a distance as to admit the easy concentration of the yarns, is the tube just spoken of, which is united to a graduated instrument, called by Mr. Huddart a register, on which there is an index to denote the proper angle of twist during the process, and which is also used to regulate the increased angle of the next process. The yarn reels were placed individually in a stationary frame at the head of the rope-ground; and it appears that the register was to be conveyed onwards towards the yarn frame, as the strand was twisted by the hook of a sledge, at the end where the process commenced, until the whole strand was made.

This part of the process is similar to Balfour's, which Mr. Huddart perfected by giving to the mass of yarns, thus formed into a strand, an additional twist, by which the strand was shortened, and provision made for the effects described to be produced by the reduction of its diameter on being stretched.

In point of principle the plan described by Mr. Huddart was complete, but his mode of carrying that principle into effect was so far complex and laborious, that, excepting the making a few ropes by way of trial, and which proved far superior to the common manufacture, the invention laid dormant and was relinquished. Mr. Huddart's specification also included a method of twisting the yarns, during the process of their being formed into a strand, as a preventive to their loss of strength by untwisting so much as the countertwist of the strand would otherwise occasion. (See *Repertory of Arts*, vol. iv. Second Series.)

Chapman's
Patent.

In 1797, Mr. William Chapman, of Newcastle, obtained a Patent for "laying, twisting, or making ropes or cordage of any number of yarns or strands, or any number of threads tarred or untarred, from the size of a cable down to the smallest line, composed of more than one thread." This invention was principally to reduce the charge of labour, and to render rope-grounds unnecessary. The strands revolved round their own axes only, and the rope was formed by the revolution of a distinct axis or frame on which it was coiled; it was capable of making, on the common principle, shrouded ropes and cables of any size, and dispensing with the use of a rope-ground. The essential difference between this invention and those described above is, that the parts of the machine which twist the strands are less cumbrous and complicated than by the planetary revolution of the strand frames; but whatever is gained by

their being stationary, is lost on the other hand by the necessity of giving a rotary motion to the rope, and the greater difficulty of coiling it away; more particularly in large cordage, in which the advantage lies with the planetary method.

Mechanical
Processes.

In the following year, Mr. Chapman obtained another Patent for "laying, twisting, or making ropes and strands of ropes, and of coiling up such ropes and strands of ropes during the process of making." The invention consisted first in tarring the yarns in such a manner as to cause them all to wind up singly, as they should come from the tar-kettle; which facilitated the process of manufacturing rope in any way and gave all the yarns a full bearing in the strand. Secondly, it consisted in making the strand separately in two distinct ways by house machinery, viz., either by having the yarns on separate reels fixed on a platform, supported on or in the revolving shaft or frame, by which, after the yarns were concentrated to a focal point, the strand was to be twisted, and from thence progressively drawn forward, and wound up as made by machinery in a stationary position; or by fixing the reels in stationary frames, and conducting the yarns separately to one general focus, over or opposite to a revolving shaft or frame, in which the strand has to be wound up as made, and which, as a most essential part of the invention, contained the machinery which was to haul forward the yarns composing the strand. These two (and a combination of them) included all the possible methods by which a strand could be made, without a rope-ground, so as to give each yarn a different length in the strand according to its distance from the centre.

Second Pa-
tent by Mr.
Chapman.

Something like the latter had been used to wind up, with a small twist, a number of yarns preparatory to their being made into a strand; but its hauling forward machinery consisted in two rollers on a stationary and separate frame, close to the opening in the top of the axis of the revolving shaft, which twisted the yarns prepared for a strand, and contained the reel on which it was wound up. The two rollers which compressed and brought forward the yarns necessarily drew them out of the same length, and prevented the yarns being twisted into a mass in any other way than on the old defective principle.

On obtaining this Patent, a machine that received its motion from a crank, and which was erected in a warehouse in Newcastle, for making ropes of five inches girt and under, was tried, and a few ropes for experiment, and some large strands, were made; which latter, on being broken by suspended weights, gave a very favourable result; and the inventor, subsequently simplifying his apparatus, Messrs. Hood and Co., of Newcastle, adopted the machinery, and the same was afterwards adopted in the King's yards.

Mr. Balfour obtained a second Patent, in 1798, for "improvements in the operation or working part of a machine formerly invented by him for making and manufacturing ropes and cordage;" which contained nothing more than the last-described method, except mentioning circumstantially his manner of turning the strand hooks, and of heaving the sledge backwards, which was also by a capstan; and like the one to which it is compared, as not differing, it leaves the backward motion of the sledge and the twisting of the strands to be regulated by the eye of the workmen; which, of course, must be defective, from having so uncertain a criterion. Mr. Balfour had previously tried in the King's yards his

Balfour's
second Pa-
tent.

Manufac-
tures.

Chapman's
third Pa-
tent,

first method, and that failing of the desired success, he effected the latter, for which he received a considerable reward from the Navy Board.

Mr. Chapman, seeing the imperfection of this first invention of the backward motion of the sledge, which is the most simple method of forming strands on a perfect principle, conceived the idea of so regulating the motion of the sledge backwards, that it must at all times travel neither more nor less than the speed predetermined; so that for every revolution of a strand, the sledge should retire precisely the length of the axis assigned to it, and of course occasion the twist to be uniformly regular; the close approximation to which is an object of importance in the acquisition of strength.

For this he again took out a Patent in the same year. The first object, that of uniformity of twist, he attained in the following manner, *viz.*, by stretching a rope, which, he called a ground rope, the whole length upon the floor of the ropery. This was passed, in the form of the letter S, partially round two or more grooved wheels with horizontal axes, fixed with other apparatus on the common machine for making ropes, technically called a sledge; but which, for this purpose, is fitted with wheels to travel on a rail-road. The grooved wheels press against each other to bind the rope, and have upon their axes tooth wheels connecting them with each other, and finally with the hooks for turning the strands; which, in this instance, are all turned by one great crank intervening between the hooks, and the wheels appropriated to the backward motion and connected with the ground rope. Thus, when the hooks were turned by the crank, the sledge was also drawn backwards by the turning of the grooved wheels, which received any determinate motion to that of the strand hooks by means of changeable wheels easily taken off and on.

In the preceding instance, the labour of the men is relieved by a rope leading from the sledge to a horse capstan, at the foot of the ropery. In consequence of the ground rope (which is capable either of drawing the sledge forward, or retarding its motion) the horse cannot draw the sledge faster than it ought to move; but his spare power is given in aid of twisting the strands through the intervention of the wheels, which connect that operation with the backward motion.

Machinery
described.
Pl. lxxviii.
Fig. 3, 4,
5, &c.

(1055.) The principal parts of this machinery are represented in plate lxxviii. fig. 3, 4, 5, &c.

Fig. 3 and 4 show the methods of stopping the twist of the hemp.

Fig. 5 the gripping sheaves to hold a rope from slipping, and which (but in a greater number) are used on the sledge in fig. 6, which is a side elevation of the tackle board at the head of the ropery, and of the sledge departing from it to haul out and twist the strands. In this figure, *a* is the tackle board, with a yarn guide and press blocks upon it, and with the lever to weight the blocks according to the magnitude of the strand. The upper half of the block rises or falls (perceptible only by the lever of the weight) with every incidental variation of the thickness of the strand, so that the resistance is always uniform, notwithstanding the interposition of two or three thick parts of yarns. *c c* the ground rope by which the sledge *b* is hove out by the motion of the wheels over which the ground rope passes, and which motion keeps its due pace with the turning of the strand hooks. *d* is a small windlass to tighten the ground rope, the other end of which is made fast at the foot of the rope-ground.

Fig. 7 is a plan of the tackle board and sledge, with part of their apparatus. Mechanical Processes.

Fig. 9 a plan of the lower half of the press block.

Fig. 8 an elevation of the upper and lower part of the press block.

Fig. 11 the yarn guide, or perforated plate, through which the rope yarns pass individually to concentrate at the press block.

Fig. 10 one of the strand frames for making a rope on the new principle at one operation.

A shows the upper division of the frame, with its reels, yarn guide, press blocks, and lever and weight, to make a primary strand after Mr. Balfour's principle, which, with the other two upper divisions, receives its motion from the wheel *i*.

B is the lower division of the frame, with its sheaves, round which the strand passes to compel it to receive the additional twist put into it by the wheel *h*, which is on the same axis with *i*. *g* is a loose wheel on the same axis with *h* and *i*, and which receives its motion from the wheels *e* and *f*, which are connected together, and move freely on the axis of the lower division B, and receive motion from a bevel wheel on the lower sheaves, round which the strand passes; and the rope (or three strands combined under the extremity of a fixed top) is drawn away by the machinery of the rope frame in which the rope is wound up as made. The use of the described machinery is to compel all the three strands to come forward with an equable motion, without which one strand would appear higher than another in the rope. A is a platform on which a coil of shroud-laid rope may be placed for the purpose of making a cable, in which case the yarn guide is taken away, and both divisions of the frame perform the same revolutions. The end of the rope is passed through the centre of the coil, and of the axis of the frames, which are hollow.

Fig. 12 and 13 show a spindle calculated to spin and take away a rope yarn, with any determinate number of turns, from women or children in a stationary position.

Mr. Chapman having, by his last Patent, invented an accurate method of proportioning the backward motion of the sledge to any predetermined twist of strand, conceived that it would be a great improvement to apply the power of a steam-engine to such locomotive machinery as is necessary in rope-grounds; and having discovered an easy method, he, conjointly with Mr. E. W. Chapman, on July 26, 1799, took out a Patent for it and other inventions, under the title of "A method or methods of making cords and ropes and cordage, both tarred and untarred, from the spinning of the yarn inclusive, to the finishing of the rope or cordage." This new method consisted of many parts. The first was an improvement in spinning the yarn, which, in the usual mode of spinning with the hemp round the waist, has all the imperfection of the mode of forming strands according to Mr. Balfour's method; each fibre of hemp being drawn out of different lengths into the yarn, accordingly as its distance from the centre required, similarly to that of the respective yarns forming a strand by the method mentioned, which is immediately apparent on untwisting a piece of yarn as the outward fibres will become slack; therefore, as the yarns composing a strand are necessarily untwisted by the countertwist of the strand when laid, it followed that the remedy of this imperfection was a desideratum.

Mr. Huddart, in his Patent of 1793, had, as already related, retained the strength of the yarns by giving

Manufac-
tures.

Another
Patent by
Mr. Hud-
dart.

each separate yarn a countertwist to the strand during the operation of its being made. This method was capable of producing the effect intended, but was too complicated, and required too much room to be carried into effect on an extensive scale.

The method now invented was to effect the end, in the act of spinning, which was done by women and children in a stationary position, one to each spindle and bobbin. The double twist was made by dividing the spindle, and giving it two separate motions, or it was done by a second process. Superior strength was thus obtained, as will appear by the following experiments made before Mr. Watson Fenwick, master rope-maker to his Majesty's yards at Chatham.

Experi-
ments.

(1056.) *Experiments.*—On April 29, 1801, Mr. Fenwick spun a thread of yarn, at Willington ropery, of the usual size, from the common wheel, and another on the double spindles; on the first spindle putting in ten turns per foot, as drawn from about his waist, and on the second spindle six additional turns. A piece of each was then broken in the state in which it was spun; the strength is shown in column No. 1. Another piece of each was then broken, after taking out two turns per foot, the strength of which appears in column No. 2.

	No. 1.	No. 2.
Common spun . . .	135 pounds	100 pounds.
Machine spun . . .	205 „	220 „

The deduction is obvious, the machine-spun yarn of the two twists being not only the strongest in its original state, but it gained strength by twists being taken out of it, as must be done in making them into a strand, whilst the other, by the same process, lost strength.

On the mean of four pieces of machine yarn, of the usual size of eighteen threads to the strand of a three-inch rope, which were tried subsequently to the preceding,

	Pounds.
The yarn, with the twist it had from the machine, broke with	194
The same yarn, with three turns per foot taken out	235
Hand-spun yarn of the same size, and spun from the same parcel of hemp, which was remarkably good, bore as under:	
As spun	175
With three turns per foot taken out	128

This process, however, incurring an extra expense, was never practised; but some portion of the effect of the double twist may be obtained in the common process of spinning, by giving the whirls whilst the spinners go backwards as slow a turn as the men can admit of without the threads breaking, and causing them, when the threads are spun to their full length, to continue until the additional twist be put in, or leaving a boy for that purpose to attend every four threads, (the number usually wound up together,) and then to follow them in.

It has already been stated that strands, made on the new principle, compared with those after the old method, possess individually as strands a superiority of strength of upwards of three to one, when each contained 144 threads; but, when made into ropes, that disparity is reduced to considerably less than two to one.

It also follows that in yarns this individual superiority is reduced when made into strands.

Hand-spun yarns are rarely spun uniformly, and, when broken individually, necessarily give way in their

VOL. VIII.

weakest parts, though only a small portion of their length, but, when combined in a strand, they then exert the average strength of all their parts, so that, on experiment, a well-made strand has been found to bear more than the sum of the individual strength of pieces of two feet length of the same yarns, although, theoretically, the strand should be considerably weaker.

The most easily available parts of the improvements stated in the specification of this Patent were,

1. The application of an endless rope (moved with considerable speed, and reaching from end to end of the rope-ground) to machinery in any part whether stationary, or changing position as ropers' sledges necessarily must. This was effected by passing the bight of the endless rope round suitable grooved wheels on the sledges, and thus giving motion to the machinery.

2. Correspondent machinery at the head of the ropery, to the axes of which the ends of the strands were attached during the making of the rope, was so contrived that the axes possessed the capability of varying their respective revolutions, during the act of moving, so as to admit of any of the strands being tempered and brought to a fair bearing.

By these means all ropes, from a small size to the largest, are capable of being made, either upon the old or new principle, without the aid of more men than necessary to attend the machinery, and take out and put in the stake heads, as the top (or implement round which the strands twist themselves into a rope) progressively moves up the rope-ground, which, like the rest of the movable machinery, it does upon a railway.

The advantage of this process is apparent, first, as each respective motion and comparative revolution of strand and rope is predetermined and fixed by changes of wheels, every part of the work is conducted in a uniform manner and not liable to mistake, as tables are made out, stating what wheels are to be used; and, secondly, in place of 200 men, which are usually employed in closing a twenty-one inch cable, fourteen are only required, and they can also coil it away with the help of the steam-engine, which is only of eight-horse power.

(1057.) *Manufacture of flat ropes.*—In many cases a flat rope is very desirable, as in drawing up coals, &c., from mines, and several propositions have been made and Patents taken out for the formation of them. The first of importance was by Mr. John Curr, of Sheffield, for a method of forming and making a flat rope, intended to be used in drawing coals and other minerals and water out of mines of any kind. His specification says, "The said flat ropes may be formed by connecting two or more small ropes sideways together, by sewing or stitching, lapping, or interlacing with thread or small ropes, &c."—He then describes his machine for stitching them together.

It was found necessary to make the constituent ropes alternately of a right-hand and left-hand twist, to keep the flat rope in a quiescent state; and in this form, composed of four small shroud-laid ropes, these were used for some years, in the Midland Counties, for drawing coals: these ropes wind up in a spiral on themselves.

In 1807, Mr. William Chapman and Mr. Edward Walton Chapman, of Newcastle-upon-Tyne, obtained a Patent for "a method or methods of making a belt, or flat band, for the purpose of drawing coals or other minerals up the pits or shafts of mines, and for raising of heavy articles in any situation whatever."

Mechanical
Processes.

Manufac-
tures.

This invention consists in the combination of two or any greater number of strands of shroud-laid rope (*viz.* of primary strands composed of yarns twisted together) placed side by side, so as to form any determinate breadth of belt or flat band, and, in a locomotive machine, for stitching or rivetting them together whilst stretched at full length.

The primary strands composing the belt should, in general, be alternately twisted the contrary way to each other, and the yarns should be twisted the contrary way to the strands they compose. The peculiar advantages to be derived from these flat belts arise from the following circumstances, *viz.*, "that the loss of strength, by the combination of these strands into a shroud-laid rope, is so considerable, that, exclusive of the reduction of length from being twisted into a rope, which is usually about one-sixth, the strength of two strands, made in such a way as to make all the yarns bear an equal tension, or nearly so, will, when laid side by side, be nearly equal to that of three such strands combined as a rope; from which result the chief advantage in forming the strands into belts, instead of making them into ropes." Finally, "all that this invention consists of is, the use of strands laid side by side, so as to acquire a strength which ropes used in this manner would not have." And also in the invention of "the truck or frame, with its apparatus for combining speedily and correctly together any requisite number of strands or other flexible substances laid side by side."

In the preceding extract from the specification, it appears that the invention rests on two points: one of which is, that the machine for uniting the strands together is locomotive, by which means strands, or other flexible substances, may be united together, whilst stretched at length under an equable stress, so as to take away their liability to disunion, from the breaking of the stitches or other fastenings, on receiving sudden jerks. The other result of this invention is, that by it belts are formed on that principle which gives their immediately constituent parts the greatest possible strength attainable from rope yarns; because a primary strand, made after the perfect manner described in the preceding columns, is of greater strength than would be produced by the same yarns extended straight by each other, and bound at intervals into a cylindric mass, called by seamen a salvagee; although Duhamel and other writers have supposed the latter to be the strongest combination of yarns, which it certainly was in large combinations before the recent improvements. At present it is not so, because rope yarns are rarely if ever of uniform strength for any great length; and therefore, when acting individually, as in a salvagee, each yarn must break in the weakest part: whereas, in a strand on the preceding principle, the small portion of strength that is lost by the oblique direction of the outside shells of yarn, is much more than counterbalanced by the yarns binding each other, so as to prevent slipping; and consequently, by their acting with a force equal to the mean strength of each yarn, which, as the extent of the weak parts is in general but a small proportion of their whole length, will conjointly give a force considerably beyond the sum of the resistances of the weakest parts of each yarn. Finally, the utility of this invention chiefly rests on the superior strength derived from the novel combination of certain constituent parts of a well known whole, which is perfect in itself, *viz.*,

a shroud-laid rope, but whose constituent parts are imperfect, and cannot be brought into use singly, because, without some further combination, they would untwist and become useless. The decrease of strength, arising from three primary strands being twisted together into a hawser or shroud-laid rope, is much beyond what it ought to be theoretically. The reduction of strength should be similar to the decrease of length, which commonly is one-sixth or less, and it is difficult to account satisfactorily for the excess of deterioration: but the same defect takes place in the combination of three hawsers, or shroud-laid ropes, when they are formed into a cable. This has been satisfactorily proved by breaking many cables, from six to eight inches girt, and their strands separately, at Willington ropery. The ropes were made on the principle of causing the yarns to bear equally; and the result of many trials was, that one of the cablets bore five per cent. more than twice the strength of one of its strands, and, in the other instances, they generally were from five to ten per cent. deficient of twice the strength of one strand; from which is proved the impolicy of continuing the old method of making the lower shrouds of large ships cable-laid, and sometimes the top-mast shrouds; because, if made hawser-laid, three-fourths of the weight of rope would be much stronger.

An immense number of Patents, besides those above mentioned, have been taken out, which our limits will not allow us to particularize; in several cases the same person taking out several, as was the case with Mr. Chapman, Captain Huddart, Mr. Belfour, Mr. Curr, and Mr. Grimshaw, of which, however, that of Captain Huddart, for cables, was considered the most scientific: but, as we have already stated, the introduction of the iron cable has so much altered the demand, that in general the machinery for hempen cables is nearly useless. We shall conclude this article by the following Tables, showing various particulars connected with rope-making, strength of ropes of different sizes, &c.

Mechanical Processes.

Hat Manufacture.

(1059.) The manufacture of felt hats, which is the only kind we shall describe in this article, is an exceedingly curious process, and is carried to a very considerable extent in this Country, where the use of this sort of covering for the head is more general than in any other nation in Europe; for not only are felt hats the universal covering amongst the upper and middle classes of the English, but the peasant likewise commonly considers such an article of dress as indispensable, although, perhaps, of late years, straw hats have, in some measure, supplanted the felt hat in our country villages. For the following interesting historical sketch of the use of hats, the process of felting generally, and for the process of hat-making both by hand and machinery, we are indebted to Arthur Aikin, Esq., Secretary to the Society for the Encouragement of Arts, &c., being the subject of one of his instructive lectures delivered before the members of that Society.

Early use of hats.—The use of hats, that is, of caps with brims to them, is of very ancient date among the Greeks; the Dorian Tribes, probably as early as the Age of Homer, were characterised by the broad-brimmed hats which they wore when on a journey. The same custom prevailed among the Athenians, as is evident from some of the equestrian figures in the Elgin marbles. The Romans appear in general to have used no covering for the head except a corner of the *toga* or upper garment; but at sacrifices and festivals they wore a bonnet or cap, and this being permitted only to freemen, part of the ceremony of manumitting a slave consisted in putting one of these caps on his head. But on a journey, the Romans were accustomed to wear a hat with a margin wide enough to shade their faces from the sun, called *petasus*.

In the Middle Ages, the bonnet or cap with a narrow margin in front appeared to have been in use among the laity, while Ecclesiastics wore hoods or cowls; but Pope Innocent IV., in the XIIIth Century, allowed to the Cardinals the use of scarlet hats; and about the year 1440, the use of hats by persons on a journey appears to have been introduced into France, and soon became common in that Country, whence probably it spread to the other European States. The cap of the Ancients was certainly made of wool, and this as well as the hat was probably knitwork. When felt was introduced as a material for hats is not known, but it is stated that the hat worn by Charles VII. of France, on occasion of his triumphant entry into Rouen in 1440, was of felt.

(1060.) Concerning the origin of felt little is recorded, and that little is, perhaps, not greatly to be depended upon.

A person, some call him a Monk, having used some carded wool by way of socks, found that the fibres, by long friction between the foot and the shoe, had matted together so as to produce a firm texture like cloth, and from this hint arose the manufacture. Specious as this account or tradition may appear to be, it deserves to be remembered that the Turcomans inhabit tents covered with black or white felt, and that some of the wanderers among the Crusaders may have brought the art of felting from Asia to Europe.

In order to understand the mechanism of felting, and to qualify us to judge of the efficacy of the processes by which it is brought about, it will be necessary to enter

Manufac-
tures.

into some preliminary inquiries respecting the structure of hair and wool; and for these we are chiefly indebted to a short paper by M. Monge, published in the *Annales de Chimie* for 1770.

If we take a common hair of the head, and, holding it fast by the root end, draw it gently between the finger and thumb, it passes through smoothly and with hardly any sensible resistance or interruption; whereas, if we reverse the motion by holding the hair by the point and drawing it from point to root, a very sensible tremulous resistance will be experienced, accompanied by a creaking kind of sound; again, if we place a hair loose between the finger and thumb, and then, by alternately bending and extending them, give them a backward and forward movement, the hair will be put in motion; and this motion will be always from root to point, whether the root be in one or in the opposite position with respect to the two rubbing surfaces. A fibre of wool likewise, in similar circumstances, always moves in one direction. Every schoolboy knows that an ear of a barley-corn, if put within his sleeve at the wrist, soon travels upward to his armpit; and that a single awn of barley, when rubbed in the direction of its length between the finger and thumb, will move only one way, that is, from root to point. The awn of barley is visibly jagged at the edge like a saw, the teeth pointing obliquely upwards, and this particular conformation is manifestly the reason why it is capable of motion in one direction but not in the contrary. A similar structure might be expected in hair and wool, but even the microscope fails to detect any thing very satisfactory in this respect; we frequently, indeed, see, or seem to see, transverse lines, and these may, perhaps, be rings of fine points, or edges of scales; or the structure may be so minute as wholly to elude our sight, although we are quite certain from the effects what the general arrangement of the parts must be; wool in the yolk, that is, with the natural grease of the sheep adhering to it, will not felt, because in this state the asperities of the fibre are filled and smoothed over, just in the same manner as oil diminishes and almost destroys the action of the finest files. But fine wool, that has been properly scoured, has so strong a tendency to mat, or intertwist, or felt, for all these words only imply various degrees of the same thing, that it cannot be spun into an even thread without being previously oiled sufficiently to suspend this tendency. Another example of the facility with which wool felts is, the common flock mattress, which is made of carded wool sewn up in ticking; the warmth and slight motion which it gets by being lain upon are sufficient to cause the fibres to accumulate round certain points, whence result those knobs and lumps of imperfect felt which render it necessary after a time to empty the bag and recard its contents.

A piece of woollen cloth that has undergone no process after that of weaving, may without difficulty be unravelled; but after it has passed through the fulling mill it is no longer subject to this action, the filaments of which each adjacent thread is composed being entangled together by a species of felting. The result of this is, that the cloth shrinks in length and breadth, but becomes proportionally thicker and more dense. The higher the heat is to which the cloth is exposed, and the longer it is continued, the more complete does the felting become; on which account it is that the modern practice of giving a gloss to woollen cloths by rolling them up very tight and then boiling or steaming them for some

hours, gives them a compactness and leathery consistence, in which all the advantages both of felt and of woven cloth appear to be united. Mechanical
Processes.

But the structure of wool and hair, as already described, is not of itself sufficient to account for the formation of felt; on the contrary, it might be expected that the filaments being, when put in motion, free to move only in one direction, should continually diverge more and more from one another. This would actually happen in an attempt to make dense felt of unprepared hairs of any kind, because all hairs are straight, or rather have only one gentle curve from point to root, and likewise possess a considerable degree of stiffness or elasticity. The fibre of wool, on the contrary, is naturally crinkled, or of a zig-zag figure, which it retains with great pertinacity, for, if drawn out till straight, it immediately contracts again to its former figure on being let go. Now this figure, besides opposing a great resistance to the progressive motion of the filament, must have a continual tendency to change the direction of such motion. The result of this would be the formation of a ball, if the pressure were equal on all sides, or a plate or layer, if the chief pressure were only in two opposite directions.

(1061.) We now proceed to describe the Art of hat-making; in which we shall enter so far into its details as sufficiently to give the reader a clear and satisfactory view of the several stages of this very important manufacture. Process of
hat-
making.

Hats are worn in this Country by people in every rank of society, and till within the last thirty or forty years the only essential difference between them was in quality, and consequently in price; the most costly being made of the best materials, and by the best workmen, while the cheaper ones were of inferior materials, and by inferior workmen; of late, however, the increased price of beaver has led to the substitution of silk for the roughing or nap of felt hats; and a diminution of weight has still more recently been obtained by the substitution of silk or hemp as the material of the body of the hat. We may therefore distinguish five kinds of hats: the beaver hat, of which the body is felt and the nap of beaver; the plate hat, with a body of felt and a nap generally of musk rat, neuter, or some other inferior fur; the felt hat, with a body of felt and without any nap; the silk hat, with a body of felt and a nap of silk plush; and, lastly, a hat with a body of hemp or waste silk and a nap of silk plush.

The general mode of making the three first kinds being the same, we shall give as full a description, as our present object requires, of making the finest or beaver hats, after which a few words will suffice to describe the difference between these and the other two kinds. The material of which the body of the hat is formed are lamb's wool, Vigonia wool, and red wool, *i. e.* the woolly hair of a species of camel, a native of the Andes, the different varieties of which are known by the names of lama, vicuna, and pacos, and rabbit's fur. The nap, or, to use the technical word, the *roughing*, consists chiefly of beaver down mixed with the better qualities of neuter hair, and the long down from the back of the English hare. The wools are shorn from the live animal, but the fur or hair is taken from skins, by first drawing out by the roots, by means of a blunt knife, the long and coarse hairs, which are rejected, and afterwards shaving off, with a very sharp knife, the down or finer hair for use. It is by no means a matter of indifference whether the down is drawn out of the skin or shaved

Manufac-
tures.

off, since in the former case the down would have the bulbs or roots attached to it, and thus would with great difficulty make its way among the other materials. Rabbit's fur, although very tender, pliable, and possessed of but little elasticity, will not felt near so readily as wool; and as this is the only fur admitted into the body of the hat, which ought to be made as dense and compact as possible, a part of the rabbit's fur is subjected to the action of moderately diluted nitric acid, or of acid nitrate of mercury. This is done by dipping a brush in the liquor and drawing it lightly in one direction over the fur while yet on the skin. The acid thus acts chiefly on one side of the filaments, and by weakening them on that side disposes them the more readily to bend, double, and change their direction during the operation of felting. The fur thus treated has its colour changed to orange-red, on which account it is known in the trade by the appellation *carroted* fur. That which is imported from Holland is esteemed the best. The only kind of wool admitted into the finest hats is lamb's wool, from Spain or Saxony. It is very carefully washed, scoured, dried, and carded, before it comes into the possession of the hat-maker.

First
process.

The first process in the manufacture is weighing out the requisite quantity of materials for each hat: more than half consists of rabbit's fur, plain and carroted, about one-fourth is wool, and the remainder is made up, according to circumstances, of red wool, and sometimes a little carded silk; but often the only materials are rabbit's fur and lamb's wool. The bowing room has windows only on one side, beneath which is extended a table or counter, divided by partitions into spaces about five feet long, one for each workman. The rabbit fur being thrown in a heap near the left-hand partition, the workman takes a bow, somewhat of the shape of a fiddle-bow, (but with only one string, and much thicker in proportion,) in the work frame; its length is above six feet, and in order to render it more easily manageable, it is suspended by a strong cord. This bow being brought over the heap of hair, the workman gives a strong vibration to the string by striking it with his thumb or with a knobbed stick, the effect of which is to put in motion and completely separate from each other all the hairs that it touches; this is continued till all the lumps and clots are broken down so as to leave the hairs separated and lying as lightly over one another as possible. A light wicker frame, like a common fire-guard, is then employed to sweep the hair a little on one side, in order to make way for the wool, which is bowed in the same manner as the hair, but with a larger bow having a stronger string. The hair and wool are then laid one on the other by means of the wicker frame, and are again bowed till a complete and equal mixture of the two materials has been brought about and an equal distribution has been made over the space that they occupy. The heap is now brought to an even surface by light pressure with the back of the wicker frame, and then covered with an oil-cloth, called a *hardening* skin. Pressure, at first very gentle, and increasing by degrees, is made on the oil-cloth by the hand of the workman, till in a short time the fibres have intermixed, forming a layer which, however, it requires care and practice to handle without tearing. The hardening skin being removed, a piece of damp brown paper, shaped like an equilateral triangle, is put on the layer, the edges of which are folded over so as to cover and enclose the paper except on one side; in this state it is folded up in a damp cloth and worked by hand,

Second
process.

pressing and bending it, rolling it up and unrolling it so as to give every fibre an opportunity of intertwining more or less with those in its neighbourhood, and thus of forming a thin though imperfect and loose felt. The use of the wetted paper is now evident; for without it the conical cavity, which is afterwards to form the inside and brim of the hat, would be obliterated by the mutual felting of the two interior surfaces. This manipulation is called *basoning*, and the triangular *body*, which is the result of it, should be twice as large as it is intended to be reduced to by the next process.

Mechanical
Processes.

The next process is called *planking*. The apparatus consists of a boiler of lead, or lined with lead, surrounded by seven or eight inclined planes of *plank*, each wide enough for a man to work at. The boiler is charged with a mixture of beer-grounds, water, and a little sulphuric acid, which is kept, as near as may be, just on the point of boiling; the workmen have their fingers unprotected, but the palms of the hands are covered with sole leather. The beer-grounds employed by our hat-makers are only a substitute for the lees of wine used in France and other European Countries, and each appears to be efficacious only from the small quantity of acid that it contains. In some of the French manufactories the use of lees of wine is abandoned, and its place is supplied by an equivalent quantity of sulphuric acid, by which the following advantages are said to be obtained: the body is brought to its greatest degree of contraction in a somewhat shorter time, a heat less than boiling is quite sufficient, and the felt comes out of this process much cleaner, being free from the mud which it imbibes from the wine lees, and which when dry becomes a fine dust, which it is often necessary to beat out again. Our own manufacturers might possibly derive the same advantage from discarding the use of beer-grounds. The planking begins by the workman laying the felt body on the plank and sprinkling it with some of the hot liquor; he then rolls it up and unrolls it, pressing on it with the leather that is tied to the palm of his hand; during the whole of this operation it shrinks and becomes proportionally thicker and more compact. It is next dipped for a few seconds into the boiling liquor, and is then rolled and worked on the plank as before, the result of which is a still further contraction and thickening of its substance. Lastly, the scalding is repeated, and the felt is worked and squeezed by means of a rolling pin, called a *walk pin*, till it ceases to contract any further. Thus the act of felting, which was begun in the basoning, is finished in the planking; and consists of rolling and pressing, first very gently and at the common temperature, then with a greater force assisted by the action of warm acid liquor, and, finally, with the greatest force that the workman can apply and at a scalding temperature. The use of the acid is probably to facilitate the solution or removal of any oil or mucus which may be squeezed out from the hairs which, if allowed to remain among them during their working, would impede their tendency to felt. The body is then stoved till it is perfectly dry.

Third
process.

The next process is to put in the stiffening, which is a composition consisting for the most part of a saturated solution of shell-lac in spirits of wine. This is applied by means of a brush to the inner surface of the body, and sometimes to the outer likewise, after which it is again stoved; by this means the felt is impregnated with a resinous substance capable of giving the required stiffness to it, and also of rendering it in a considerable

Fourth
process.

Manufac-
tures.

degree impenetrable by rain or cold water. In the act of drying, some of the lac is generally brought to the surface, making it rough; this is removed by just dipping the body in a hot solution of alkali or borax, which loosens the crust and allows it to be got off by the use of a copper scraper, called a *draw board*. It is then a third time stoved, and when nearly dry is singed by holding it over a blaze of shavings, in order to remove the hair which stands out from the surface of the felt.

Fifth
process.

The next process is putting on the nap or roughing. For this purpose the materials, consisting of half or three-fourths of an ounce of beaver fur and some fine cotton, mixed occasionally with some of the other furs already mentioned, are bowed down, and then by the hardening skin are made into a very tender imperfect felt of the shape of the body intended to receive it, but about three inches longer; a strip of this width being then torn off from the bottom of it, the remainder is just sufficient to cover the body, while the strip is reserved for the under part of the brim of the hat. The roughing being thus prepared, the body is softened by dipping it in the boiler, and is then covered with the roughing, the strip being applied on the lower part of the inside. It is then taken to the plank, and the roughing is fixed to the body by first putting it down with a wet brush, then rolling it in a hair-cloth, dipping it in the hot liquor, and working it about as already described in the felting process, till the whole of the cotton is separated.

This is an operation that requires a good deal of care and experience, as will be evident by considering what happens in the course of it to the hairs that compose the roughing. When first laid on they form a horizontal layer, the individual hairs lying in all directions. As soon as the rolling and pressing begins, each hair is put in motion from root to point, and enters the substance of the felt body. These hairs have considerable stiffness and elasticity, and are moreover not weakened by the application of nitric acid; they therefore proceed in a pretty straight course into the felt, with the substance of which they form a union, but by a sufficiently long continuance of rolling and pressing they would actually pass through the felt and be found on the inside instead of on the outside. When the process has been continued long enough, the hairs will have penetrated by their root sufficiently far to secure them from being drawn out in brushing the hat. Up to this stage of the process the body has merely the shape of a cone, without any resemblance to that of a hat, but the next process, which is *blocking*, begins to bring it into form.

Sixth
process.

This is done by pressing in the cone so as to form it into three or four concentric ridges and furrows; then the point is pressed out by the finger, and as it gets wider the hand is used, by means of which, at length, the cone is drawn out nearly to a cylinder; it is then drawn over a wooden block and tied on, and in this state is ready to be dyed. The ingredients of the dyer's copper are water, sulphate of iron, verdigrise, gull nuts, and logwood; and in this mixture the hats are boiled for some hours, at the end of which time they are found to have acquired an intense and beautiful black. They are first drained and dried, and then are taken off the block and transferred to the *finishing* room. Here the hat is first placed over a jet of steam to soften it, then the crown is strengthened by sticking a piece of scale-board on its under side, and securing it by a piece of linen pasted over it; a block is then put into it, and the

surface is smoothed, and a uniform direction is given to the nap by means of warm and damp hair brushes, and a plush brush called a *velours*; a hot iron is also employed for the same purpose.

Mechanical
Processes.

It is next *trimmed*, that is, the binding, leather, and lining are sewed in; and, lastly, it is *finished off* by being warmed and set up to the fashionable shape. Having thus described step by step the whole process of manufacturing a beaver hat, a few words will suffice for the plate and felt hat.

(1062.) The body of the plate hat is entirely of lamb's wool, either Saxon, Spanish, Kentish, or South Down, and after basoning, previous to being planked, is generally boiled in water and stale urine. The nap or roughing is composed of various furs, from that of the musk rat (which is only inferior to beaver down) to those of the lowest quality, according to the price at which they are intended to be sold. The felt hat is made entirely of wool, without any roughing, the nap being merely scratched up by a card, and the stiffening is glue instead of lac.

Plate hats.

Silk hats, as they are commonly called, were invented some years ago. They are hats with a thin wool body and a nap of silk. But as silk is not capable of felting, it was necessary to discover some other method of fixing it on the body. After many trials, that which has finally been adopted has been to take the silk manufactured into plush, with a pile of unequal length, and to sew it together into a cover just capable of fitting the felt body. This latter is then smeared over with an adhesive resinous mixture, and as soon as it has become dry the bag or cover of silk plush is drawn over it and fixed firmly to the body by means of a hot iron; it is then finished in the usual way.

Silk hats.

(1063.) The last variety of hat we shall mention is one for the manufacture of which a Patent has recently been taken out by Mr. Williams. The body is made of hemp, tow, or of waste silk, finely carded, or rather torn into distinct filaments; but as neither of these substances possess in the slightest degree the property of felting, the following very ingenious and simple method has been employed to form these filaments into hat bodies very even, light, and of greater strength than felt of the same thickness.

Williams's
Patent for
hat-
making.

A fan with vertical fliers is fixed in a case or box, open at top, and united below with a horizontal trunk, in which are apertures that may be opened or shut at pleasure. It is evident, therefore, that if the fan is put in motion, its effect will be to exhaust, to a certain degree, the air in the trunk, the consequence of which will be that a current of air will set in through each of the open apertures. A frame of the shape of a hat, made of sheet zinc perforated with many small holes, is placed over one of these openings, and by simple mechanism a slow motion round its centre is given to it. The carding machine delivers the filaments of silk or hemp into the air above, and a little on one side of the revolving frame. The filaments in their descent soon get into the current of air that is setting into the trunk through the perforations of the zinc frame, and are deposited quite evenly on its surface, and so rapidly, that in about five minutes a layer of sufficient thickness for a hat body is formed. A frame of perforated sheet copper is then put on, so that the layer of silk is enclosed between the two, and, though possessing in itself no coherence, is thus prevented from being in the least degree deranged. The frames are then dipped into a boiler full of a stiffening

Manufac-
tures.

mixture, the chief ingredient of which is shell-lac, and when sufficiently drained the upper frame and afterwards the under ones are removed, leaving the filaments of silk cemented into a hard, light, strong hat body, which is afterwards covered with silk plush in the manner before described.

Various
uses of felt
in the Arts.

(1064.) We have now finished what was proposed to be said on the subject of hat-making, but before concluding this article it will be well to make a few remarks on the other uses to which felt is applied. The polishing wheels of comb-makers, workers in brass, and other artisans, are covered with felt, which, by its spongy texture, retains the putty and other polishing powders better than any other substance would do. The felt for this purpose is made into sheets of various thicknesses, which are afterwards cut up into strips of the required size. Gilders' baskets, in which they shake buttons and other articles of copper with an amalgam of gold, being part of the common process for gilding such substances, are made of felt. An old hat was first employed for this purpose, but it has been found more convenient to have larger baskets made expressly for such use. Some kinds of large filters or jelly bags are now often made of felt; and a kind of paper, made chiefly of wool, is imported from Germany for the use of chemists and apothecaries; it is an excellent filter for hot liquors, acting rapidly, and is not nearly so liable to be broken through with the weight of the liquor as a paper filter. Felt, chiefly in the form of old hat, is likewise extensively used by the engravers of blocks for calico-printers, being inserted in those parts of the pattern where a large body of colour, or, rather of mordant, is to be laid. Old hat is likewise converted into an excellent polisher by dipping it into a weak solution of common alkali and then drying it. The alkali decomposes the black dye, bringing the iron, which is the base of it, to the state of oxide or rust, which remains disseminated through the whole substance of the felt.

Lastly, felt is largely and increasingly employed in sheathing ships. A great quantity of cow's hair enters into the composition of this substance, and as it felts only very imperfectly, the sheets while making are passed through a boiler of pitch or tar, which increases their cohesion. Sheathing felt is applied in coppered ships immediately below the copper. There are two most important benefits attend the use of this sheathing. In the first place, it is a complete protection against the worm, which probably is incapable of working its way against the stiff bristles which are largely introduced into the composition. In the second place, it is impermeable to water, and being at the same time very extensible, is not easily broken by the working which takes place among the timbers of a crazy ship; hence many leaks are prevented which might otherwise damage the cargo, or even hazard the safety of the vessel itself as well as the lives of the crew.

Paper-making.

History of
paper-
making.

(1065.) The Art of paper-making is of great antiquity, and probably of Chinese origin; but at what period the Chinese paper, or the art of manufacturing it, was first known in Europe, is not, perhaps, quite certain; although it is generally supposed that the knowledge of the article itself, and the process of making it, were brought from the East by the Arabs, and that the manufacture was practised in Spain during the IXth or Xth Century.

Mechanical
Processes.

Before the invention of paper, materials formed of different substances were had recourse to for the record of events, and for the common purposes of writing; such as skins, thin sheets of horn and ivory, and the Egyptian and Greek papyrus, formed from a plant bearing that name. These last, however, although used for the purposes for which we now employ paper, partook in no degree of its character in the nature of their manufacture. The skin was merely converted into parchment, and the bark of the papyrus preserved after the removal of the fibre, in nearly its natural form; whereas what is properly called paper is an actual manufacture, a new formed substance, which resembles no way the material from which it is derived, and to this kind of paper only the following remarks will apply.

It has been said that, in all probability, the invention of the Art of paper-making originated in China, and it is stated by Casira to have been introduced at Mecca in 710; but it is certain that the Chinese were acquainted with the Art long before that epoch, but it is not certain whether they were the actual inventors or had derived it from some other people. It appears, however, at all events, that, for a long period of years after they possessed the knowledge of letters, they were unacquainted with the use of any material for writing upon of the nature of their present paper; the first invention of which is said, by some of their authorities, to have taken place in about the year 95 of our Era; that it was due to a Mandarin of high rank named Isay, and that he employed, as the material of the composition, not only cotton and silk, but also the inner bark of different trees. In course of time many other substances have been employed by them, and at present, it is said that not only cotton, silk, and linen rags, but the bark, and even the wood, of the bamboo and cotton tree reduced to dust form ingredients in the manufacture of Chinese paper; and it is now well known in Europe that paper may be formed of almost any kind of fibrous material, although none seems so well calculated for the purpose as the rags of white linen. The history of paper, therefore, stands as follows, viz. that it was probably first invented in China, about eighteen hundred years ago, and it was thence brought to Mecca, with the Art of imitating its manufacture, about the end of the VIIth or the beginning of the VIIIth Century; whence the Arabs transferred it to the Northern coast of Africa and to Spain, where we have seen it was introduced in the Xth Century, or probably somewhat earlier. It is, however, doubted whether the rest of Europe originally obtained their knowledge of the invention from that Country by the way of Asia, or from Constantinople through Greece.

In the XIIth Century it appears to have become the common material for writing upon throughout Europe; but there is great difference of opinion as to the date at which cotton paper first began to be supplanted by that made from linen. According to some authorities, paper was manufactured from linen by the Moors of Spain before the Xth Century; while other writers contend for a much later origin of this improvement. "The manner of making the cotton paper," says Anderson, in his *History of Commerce*, "introduced the still better and cheaper paper made of linen rags. This last invention Montfaucon ascribes to the XIIth Century; yet others make it so late as 1417; and an octavo Treatise in English, entitled *The General History of Discoveries and Improve-*

nufacture
into Eng-
land.

ments, says, that rag paper was not invented till about the year 1452; while Rombold, in his Dissertation on Paper, printed at Berlin in the year 1744, fixes its invention to have been in 1470, though probably somewhat earlier. The cotton paper invented (A. D. 900) very nearly resembled our rag paper; but as the latter was much cheaper in its manufacture, as being made of rags, which before were thrown on the dunghill, it soon drove out of use the cotton paper, which necessarily bore a much higher price."

It was long before the manufacture of paper was introduced into this Country, the first known erection of a paper-mill having been in 1588, at Dartford, in Kent. "But about the year 1690," says the writer we have just quoted in another place, "there was scarcely any other kind of paper made in England, except the coarse brown sort; but the war with France occasioning high duties on foreign paper, the French Protestant refugees settled in England chiefly, and also our own few paper-makers now began to make white writing and printing paper; which in length of time has been brought to so great perfection, both for beauty and substance, that in our own time (1764) we import only certain kinds of Genoa and Dutch paper, which, however, bears but a small proportion to all the paper used in the British dominions. How great a saving this has proved to Britain may partly be conceived from what has been often formerly affirmed by such as are well acquainted therewith, viz., that to France alone, from which we now take none even in time of peace, we paid annually to the amount of one hundred thousand pounds, for paper only." In 1721, according to the *British Merchant* published in that year, two-thirds of all the paper used in England was made at home, and this proportion is said to have amounted to 300,000 reams. "In 1783," says Mr. McCulloch, (*Dictionary of Commerce*, 2d edition, p. 875,) "the value of the paper annually manufactured was estimated at £780,000. At present, besides making a sufficient quantity of most sorts of paper for our own use, we annually export about £100,000 worth of books. We still, however, continue to import certain descriptions of paper for engraving from France, and a small supply of paper-hangings, the duty on both amounting to about £2800 a-year. In 1813, Dr. Colquhoun estimated the value of paper annually produced in Great Britain at £2,000,000; but Mr. Stevenson estimated it at only half that sum. From information obtained from those engaged in the trade, it appears that the total annual value of the paper manufactured in the United Kingdom, exclusive of the duty, may at present amount to about £1,200,000 or £1,300,000; and that we have about 700 paper-mills in England, and from 70 to 80 in Scotland; but the number in Ireland is inconsiderable. Of these mills, few have been lately unemployed, and about 27,000 individuals are supposed to be directly engaged in the trade; but in addition to the workmen employed in the mills, the paper manufacture creates a considerable demand for the labour of mill-wrights, machinists, smiths, carpenters, iron and brass-founders, wire-workers, woollen manufacturers, and others, in the machinery and apparatus of the mills."

In a passage quoted above from Anderson, the substitution of linen for cotton in the manufacture of paper was spoken of as having at first greatly lowered the cost of the manufactured article, but now that cotton has become much more plentiful and much cheaper than

linen, it has been again resorted to, we believe, to a considerable extent, in the manufacture of printing paper, and even of writing paper; its only recommendation, however, is its cheapness, for from the comparative weakness of the fibre in cotton, paper when made from that material has far less strength and durability than when made from linen.

It appears that about four-fifths of the linen rags, from which English paper is formed, is imported from foreign Countries, principally from Italy, Germany, and the United States, the exportation of rags being prohibited in France, Holland, and Belgium by severe penalties; the exportation of rags is also prohibited in Spain and Portugal. The imported rags arrive here in close bags, already sorted, and the bags variously marked, so as to indicate the quality of the rags within; these are taken to the mills, where a further sorting takes place, and the operation of paper-making commences. This is at present in the larger manufactories carried on by machinery, but in some smaller ones by hand. So great, however, has been the advantage of employing machinery, and so great the improvement in the chemical processes to which the rags are submitted for bleaching them, that as much of the latter process is said to be effected at present in three minutes as formerly required as many weeks.

(1066.) *Process of paper-making by hand.*—The general nature of the processes of paper-making, the particulars of which will be given below, consists in separating the fibres of the rags into exceedingly fine and short filaments, by a mill constructed for that purpose, and mixing the material thus reduced with such a quantity of water as will convert the mixture to a fine pulp, which is afterwards taken up in a very thin and even layer upon a mould of wire cloth. Here the water, draining through the wire, leaves the filaments of linen so completely interwoven or felted amongst each other, that they will not separate without breaking, and when dry will form a sheet of paper, the strength and quality of which depends, of course, very much upon the material it is made from, and the equality of length and size to which the filaments are reduced by grinding, which uniformity alone can cause them to float equally in the water of the pulp, and thus distribute themselves evenly and smoothly over the wire mould when taken up by it. Such are the general principles of paper-making by hand, which it will now be necessary to describe more in detail. The entire operation may be reduced to three distinct heads, viz., preparing the pulp, forming the sheets, and finishing the paper.

In the first process the rags are sorted into qualities proper for different purposes; they are then bleached, unless, as is sometimes done, this is deferred to the next stage of the process.

The washing is effected in a mill in which the rags are ground to a coarse imperfect pulp, called half stuff, in which state the bleaching (if it has not been previously done) is effected. The bleaching is also sometimes performed in the mill while the rags are being ground. The half stuff, in this state, is again reduced in what is called the beating engine, and sufficient water is added to convert the whole to fine pulp, in which state it is conveyed to the vat, and is then in a proper condition for being formed into sheets.

When the second process is effected by hand, it is performed by a workman who takes up a quantity of pulp, already placed in a kind of cistern, upon a mould

Mechanical
Processes.

Supply of
rags.

General
process.

Manufac-
tures.

of fine wire cloth, through which the water drains away, and the pulp coagulates into a sheet of paper, being rendered uniform in thickness by a slight shake given to the mould. Another workman now takes the sheet of paper off the wire mould and receives it on a plate of felt; he then covers it with another plate of felt, evenly spread, on which is placed a second sheet of paper; and thus he continues the operation till he has made a pile, called a post, containing six quires of paper. This is now removed to a press and submitted to a strong pressure, which presses out the superfluous water and gives the requisite surface, firmness, and solidity to the paper.

The pile is now removed from the press and the paper taken out sheet by sheet, which, being laid one on the other, are again submitted to pressure in a smaller press, where they remain for a certain time, when they are removed, and are then hung up on lines to dry. This finishes the second process, and for many common sorts of paper it is the last, the article now merely requiring packing for the market; but the better sort of paper for writing, printing, &c. has to be finished, which, as we have seen, is the third process.

In what is called finishing, the paper, in parcels of five or six sheets each, is dipped into a tub of fine size and afterwards pressed to force out the superfluity; it is then again dried in the drying loft; this is not, however, necessary for printing paper, the size in this being introduced at an earlier stage. After this an examination is made of every sheet individually, and all knots and burs are removed, and the defective sheets thrown aside. A large pile is now made of the selected or perfect sheets, which are again submitted to a great pressure to render them flat and smooth; they are then taken from the pile sheet by sheet so as to form them again into a pile without turning them over, by which means new surfaces of the sheets are brought in contact with each other, and the pile is once more submitted to the press and the surfaces of the sheets are further improved; this operation, which is called parting, is repeated two or three times for the best paper, which is then counted into quires and packed ready for the market.

Such is the old process of paper-making by hand, and the principle is the same as regards the constitution of the paper in the modern operation by machinery, which still remains to be described.

Paper-
making by
machinery.

(1067.) *Paper-making by machinery.*—We have passed over, in very concise terms, the general principles of paper-making by hand, and have not described the machinery which, even in that process, is necessary in the preliminary part of the operation, because the same is employed in the modern mill in a more improved form, and we preferred to give all the machinery under this one head; we shall therefore now describe more in detail the entire operation from the first receipt of the rags to the production of perfect paper.

Sorting.

Sorting the rags is of course the same whether the final operations be by hand or by machinery. This is commonly carried on in the sorting room by women, who are placed at tables having wire bottoms through which the dirt from the rags may fall; a knife blade of large size is fixed up across the table; the rags are taken up in one hand, and such as require to be cut are run across the edge of the knife and thus reduced to their proper lengths, and the different kinds separated by being placed in different boxes. These are afterwards examined by an overlooker, who makes a further separation if necessary.

VOL. VIII.

The rags are then dusted in a machine for the purpose, consisting of a wire cloth cylinder about six feet long and four high, into which a certain quantity of the cut rags are placed, and within which are arms or spokes about twenty inches long fixed to the axis; this being set in rapid motion by being put in gear with the machinery of the mill, the rags are driven about with great violence and all the dust in them passes out through the wire cloth.

Mechanical
Processes.
Dusting
machine.

Boiling the rags is the next operation. This is generally conducted in sheds, in which there are several large chests filled with rags, into which steam is forced for the purpose of heating the mass of rags and water; after remaining in this state for some hours, they are in a fit condition for the engine, which is next to be described.

(1068.) The engine consists of a trough A A, plate lxxix. fig. 1, which is about ten feet long, four and a half feet broad, and two and a quarter feet deep; this is made of wood lined with lead. B is a longitudinal division of the engine; C is an iron roller twenty-two inches in diameter, and twenty-six inches wide; and D is an apparatus for conveying pure water into the trough, and for carrying off the foul water. The roller being set in motion, about a hundred weight of rags are put into the trough, and as much water is let in as will raise the whole to within an inch or two of the brim. The roller is not a plain cylinder, but its surface presents a number of bars or knives projecting more than an inch radially from its axis, and beneath the roller is a plate composed of bars or knives, of the same kind as those of the roller, as shown in fig. 2. When the roller commences its revolutions, of which it makes about 160 in a minute, the rags are carried with great rapidity through the knives, and as the roller is depressed upon the plate or elevated the rags are cut or bruised. Above the roller is a cover, (not shown in the figure,) in which are two frames of wire cloth communicating with the pipes at D. When, therefore, the whole mass is in agitation, the rags, after passing through the knives of the roller and the plate, are carried up the inclined plane of the division E, and the foul water passing through the frames is removed by a pipe at D, while a clear stream is continually pouring in from the same point; in this way the rags are bruised down and washed in the first engine. After this operation has been continued for a sufficient time, the water is let off, and the cleansed mass is removed to a press, for the purpose of driving out the greater part of the water which remains in it. In this state the foreign rags, though not white, are clean, and have somewhat the colour of the cloth called brown Holland.

Engine.
Pl. lxxix.
Fig. 1, 2.

It is unnecessary to observe that the rotation of the cylinder is produced by wheelwork connected with the moving power of the mill whether it be water or steam, and that in the larger mills several such engines are at work at the same time.

(1069.) The rags on leaving the engine correspond with what we have called half stuff in our general description. The mass is now, as above stated, taken to a press, and submitted to a great pressure, whereby all superfluous water and moisture is driven out, and is then placed in a close chamber to be bleached.

Bleaching.

This is effected by conveying into the chamber, by means of pipes communicating with a retort, a proper proportion of chlorine gas, common salt, and sulphuric acid, by which process the rags, however originally dyed or discoloured, are rendered perfectly white, but they

Manufac-
tures.

Beating
engine.

are subsequently placed in the washing engine to cleanse them from the chlorine.

From the last stage they are transferred to the beating engine, which resembles in every respect the engine described above, except that the knives and plate are closer together, and the roller in this operation is moved with greater rapidity. After undergoing this process for several hours, the rags assume at last the appearance of perfect pulp somewhat resembling milk, and in this state the size necessary to give a hardness and body to the paper is introduced for some kinds of paper; but for others, particularly writing paper, the size is laid on the surface in a subsequent stage, as already stated.

In the above processes machinery is employed, whether the next operations are to be performed by hand or not; but we shall not add any thing further to the preceding account of hand-made paper, but proceed to describe the modern mill, which is, perhaps, as interesting a piece of machinery as it is possible to imagine. At one end of the machine is a vat of pulp; this is let off into a cistern; from this cistern it is transferred to an endless wire cloth; as this passes along for a few feet the water drains off and the pulp begins to possess a certain consistency and solidity; it now passes through certain rollers, and much of the superfluous water is absorbed; continuing still its forward motion it is submitted to further pressure, its surface is formed, but it is still moist. It now passes over hot metal cylinders and finally emerges from the machine in a continuous length of perfect paper, or it goes still forward, enters the cutting machine, where it is cut into sheets of a proper size, according to the nature of the paper in hand. Such is the general nature of the modern paper machinery, but the reader will expect a more minute description; it must, however, be observed, that the processes differ considerably in different mills, and we must confine ourselves only to one or two of the most approved of them.

Fourdrinier and
Gamble's
Patent.

(1070.) *Fourdrinier's machine.*—This was the first successful attempt at supplying machinery to perform the duties of the deckle or mould, but it did not at first carry the process to the extent we have just described, that is, the paper was not dried on the machine, but was removed to lofts for that purpose; it contains, however, the elements of the present processes, displays great ingenuity, and is still employed; a description of it will therefore be interesting.

The pulp being prepared is placed in a large vat elevated on brickwork, in which are two agitators turned by the machinery of the mill to prevent the stuff settling and to preserve it of the proper consistency; from this vessel it is discharged by a sluice into a cistern, over the edge of which it runs in a fine smooth stream (like water over a river wear) upon an endless wire cloth, the breadth being preserved and the stuff prevented from overrunning the edges by running straps. This cloth, in the first machines, was twenty-four feet long, the part nearest the vat running over a number of small rollers to prevent its sinking and the pulp becoming of unequal thickness; during the passage of the pulp on the endless wire cloth to the extreme roller a great deal of the moisture is discharged, and it has there assumed such a consistency as to receive the impression of the finger without any tendency to restore itself by fluidity. This process, *viz.*, of discharging the water, is facilitated by a shaking motion communicated to the wire cloth by certain arrangements in the machinery which also equalizes the thickness. The water thus discharged

contains a certain portion of the pulp, and is caught in a shallow cistern below the wire cloth, and is thence transferred to another vessel, from which it is raised by an axle carrying scoops or scuppers, and taken thence back to the vat. This part, however, is not introduced into the recently constructed mills, the operation being effected in a more simple way. When the paper has arrived at the last roller, or at the end of the wire cloth, it passes between two rollers and then falls on a web of felt which carries it exactly as the wire cloth had done, and at the end it again receives another pressure in passing with the felt between two rollers; by this means a great portion of the remaining moisture is absorbed, the paper being in a state to be wound upon a reel. When sixteen or eighteen quires have been thus accumulated, the reel is removed and another substituted, the paper is cut off the first reel and sent to the loft to dry. There are a great many other appendages, &c. described in Messrs. Fourdrinier and Gamble's Patent which we think it unnecessary to describe; amongst others, circular shears for cutting the edges of the paper and for dividing it into sheets of a proper size, &c. Great ingenuity is displayed in the whole of the arrangement; experience, however, has certainly enabled subsequent constructors to simplify several of the parts, but the principle of the operation has been preserved in them all except the machine of Mr. Dickinson, which acts by means of a vacuum, after a manner we will now endeavour to describe.

(1071.) The principle adopted by Mr. Dickinson, and which, in consequence of subsequent improvements, has been the subject of a great number of Patents, consists in causing a cylinder covered with wire cloth to revolve over and just in contact with the prepared pulp, so that by a connection of this cylinder with an exhausted vessel the pulp, which adheres to the cylinder in its passage over the surface, is gently pressed and the paper rendered drier and of more uniform thickness than in the former machine. The many additions and alterations, however, which have been made by the ingenious inventor prevent us from attempting any thing like a minute detail of them; we shall content ourselves therefore with describing the general principle, and an account of his Patent of May 1811. A general idea of the cylinder will be understood by referring to fig. 3, where A is a hollow revolving cylinder made of brass and polished outside and inside. On the surface B C a great number of small holes are cut in the cylinder, and over these holes a wire cloth is neatly secured, the stuff or pulp fills the vessel d, and the water runs into the cylinder as it revolves and leaves a portion of pulp on the wire cloth. The parts E, E form a box in the cylinder which does not revolve, and the edges of the box F F touch or rub against the interior of the cylinder; c is a pipe connected with the receiver of an air-pump which exhausts the box G. When the wire cloth with the pulp on it arrives above the exhausted space G, the pressure of the atmosphere presses the pulp on the wire cloth, thereby giving to it a certain consistency and regularity. The cylinder H, made of a hard body covered with felt, then receives the sheet; when it reaches the point I it adheres more to the cylinder H than to the wire cloth; it is then pressed between the cylinders H and K and taken off at L, and finished in the usual way. This is sufficient to give a general idea of the difference of principle between this method and that of the original inventor Fourdrinier.

Mechanical
Processes.

Dickinson's
Patents.
Pl. lxxix.
Fig. 3.

Manufac-
tures.

But much has been done by Mr. Dickinson to improve his first discovery, which has formed the subject of several Patents, one of which, 1809, is perhaps the best for giving a more complete idea of his operations; this specifies seven distinct improvements, the first of which is a different way of forming the openings into his cylinder. In the preceding statement the surface of the cylinder is described as containing a number of small holes; this is altered in the present case by making the openings in another way, but to the general reader the difference is not important; we shall not, therefore, enter into particulars.

Fig. 4.

The second improvement described in this Patent consists in a more perfect mode of removing the water from the cylinder above spoken of. The ends of the cylinders having holes in their middle turn on the tube G, fig. 4; this tube has an arch or quadrant at each end within the cylinder H H to which the trough I is fixed at each end; and the tube arms and trough being all likewise firmly fixed, the cylinder in turning round will rub on the top of the trough, which should be provided with a packing of leather or other soft substance. In the upper part of the tube G there is an opening which communicates through the pipe K with the exhausted trough I and exhausting vessel worked by a pair of double-acting air-pumps. The tube G is intended for letting out the water from the inside of the cylinder instead of its running out at the ends, as proposed in the former Patent. The pipes L, L, &c. are open at their lower ends, and soldered or otherwise fixed into the tube G, which has no opening except through the cocks J, J, the orifices of which are below the mouths of the pipes L, L, &c., and consequently the whole together will act as a syphon and empty the cylinder as low as the mouths of the pipes L, L, or when the cocks J, J are shut the water which is admitted into the inside of the cylinder through the surface cannot pass out through any channel. The intent of this part of the apparatus is that the water inside the cylinder may be kept to any level between the bottom of the pipes L, L, and the height of the pulp on the inside of the cylinder, by the cocks J, J being more or less turned, and the pressure of the head of pulp on the cylinder, and the quantity of water forced through it, may be adjusted accordingly; and as the thickness of the paper depends on the quantity of fibres of rag left on the surface of the cylinder by the water flowing through it, this principle affords the means of regulating it with great precision. The exact shape of this part of the apparatus is not material, but the tube and cocks must be of large diameter, as the quantity of water that flows through in making paper by this method is very considerable.

Fig. 5, 6.

The third improvement relates to the construction of the vessel intended to contain the pulp for the supply of the cylinder. This vessel is represented in fig. 5, 6 with the cylinder in the inside of it; and instead of the cylinder rubbing against it, as formerly described, it is proposed for the cylinder to turn round in it without touching it, a motion being communicated to the former by means of a toothed wheel, which works on the tube G for an axis, and has a clutch attached to the boss which connects it with the cylinder. In the longitudinal section, fig. 5, the vessel is observed to hang on one side on the boss of the toothed wheel N, and on the other side on the tube G, and between the joints rings of leather are put to prevent the pulp or water escaping; or any other well-known method of packing

Mechanical
Processes.

may be used for that purpose. There is a piece of metal on each side of the vessel or back, shown in fig. 5, which is fixed by screws, and is intended to take off, for the purpose of getting out the cylinder, &c., when it is necessary to take the machine to pieces. The direction in which the cylinder works is shown in fig. 5, by arrows, and as the water is constantly running through the cylinder and out of the cocks J, J, fig. 4, while the machine is going, the fibres of rag are accumulating on any given part of the surface during that period of its revolution, while it is passing from the point Q to the point R, and at the point S, after the paper collected on the cylinder has passed over the trough, and has been sucked nearly dry, it is led off the cylinder by the couching roller T, to which it will adhere; the exact shape of the back is not material, and the method of giving motion to the cylinder may be varied, but that described in the drawing will be found most eligible in use. The back may be of wood or metal; copper has occasionally been made use of for this purpose. The object of this improvement is to remove the friction between the back and the cylinder, and to employ as large a proportion of the surface of the cylinder as possible in the accumulation of the pulp, so that the quantity necessary for the formation of a sheet of paper may be collected upon it in a shorter space of time than by the original method, and consequently the machine enabled to go at a greater rate. Mr. Dickinson's fourth improvement relates to the process of couching, or taking the paper off the cylinder, in lieu of the brass roller used for that purpose, as described in Mr. Dickinson's former specification, dated July 19, 1810; instead of which he now recommends a roller covered with several folds of woollen cloth, so that the surface is moderately soft and elastic. It is to be observed that the caps are made so as to fit on to the bevel at the ends of the cylinder, in such a manner that their outer surface stands exactly flush with the outer surface or periphery of the cylinder; and the couching roller T should be made rather longer than the cylinder, and the ends of the spindle worked in a grooved bearing, so that the roller may only be confined down upon the cylinder by its own weight, or by suspending equal weights at each end of it, in case its own weight should not be sufficient.

The fifth improvement alluded to by the author consists merely in the application of a well-known method of using an endless felt, which is shown in fig. 5, marked M. This felt is made to run round the couching roller T, by the pressure of which the paper is caused to adhere to it at the point S, and the paper is carried round with the felt, and receives two subsequent pressures between the pressing rollers V, V and W, W, after which it is reeled off for cutting. The Patentee makes use of two pairs of pressing rollers, the first pair of which takes only a part of the water out, because if the whole quantity were squeezed out at once, it would require the machine to move at a slow rate. The adjustment of the pressure of the first pair of rollers is necessary to be attended to, and is effected by weights hung at each end of the spindle of the top roller and that of the second pair by screws. It is to be observed that it is necessary to use a second endless felt, in order to prevent the paper sticking to the top roller V, as is shown by a line in the figure, and marked X; both these felts may be guided by any of the methods at present in use.

Manufac-
tures.

The sixth improvement relates to the method of feeding. The stuff, properly prepared and diluted with water, is delivered by one or more feed pipes *e* into the back, in such manner that the orifice of the feed pipes is below the surface of the stuff in the back. The vat should be furnished with a sluice, or some well-known method of regulating the supply of stuff through the feed pipes *e*, so as to cause as little stuff as possible to run over the waste pipe *f*. In the longitudinal elevation, fig. 5, *Y* represents a roller which works in a grooved bearing in a pit under the machine, and the weight of this hanging on the felt which goes round answers the purpose of stretching it, or the same may be done by any common well-known method. The felts should be washed while the machine is at work; and the manner adopted for the bottom felt *m*, used by the Patentee, has been to pour water upon it out by the rollers *z, z*, before it again comes in contact with the paper at the point *S*. There is no precise standard for the dimensions of the cylinder and other parts of the machine, which, in conformity to the scale of the figure, may be worked at the rate of forty-eight feet per minute, and even more. The motion may be applied to the machine by any convenient power, and by any method that causes the pressing rollers, the couching rollers, and the cylinders to move at the same rate; this is done by communicating a motion to the spindle of the bottom pressing roller *W*, fig. 5, 6, in the direction described in the drawing by arrows; and upon the spindle is fixed a chain rigger *a*, which, by means of the endless chain *b*, gives motion to the other chain rigger *c*, the spindle of which turns the toothed wheel *d*, which works into the toothed wheel *N*, and by means of the clutch before mentioned, which connects the wheel *N* with the cylinder, the latter is turned round in the direction shown in the figure. The endless felt *N* being put in motion by the pressing rollers *W, W*, will by its friction give motion to the other rollers and the upper felt *X*. It is to be observed that the suction from the trough *I* must be continued while the machine is at work, by the action of air-pumps, the construction of which is well understood and has long been practised; but they must be worked in such manner as not to exhaust too much air nor too little, and the motion adjusted accordingly. The letters of reference to the different parts of the machine are the same in the different figures.

The author's last improvement consists in certain alterations of the back, so as to enable the machine to make paper having two or more different colours in the same sheet. For this purpose the back must be partitioned off, according to the description of the paper it is required to make; that is to say, supposing it is intended to make paper having various stripes of different colours down the sheet; to accomplish this, it is necessary to have different vats or feeding vessels for each different colour of the stuff, with corresponding partitions in the back. We do not, however, consider a description of this part essential to our present article.

Different
sizes and
denomina-
tions of
paper.

(1072.) Prior to the commencement of the last century there was no duty on paper, and the sheets were made of various and uncertain size; each maker, however, distinguishing his own by introducing his name or some device into the paper, by working fine wire into the mould in which the sheets were made, the impression of which remained when the sheet was formed, as is still

practised; and from this circumstance the names of some sorts of paper derived their origin, as for example, *foolscap*, which was so called from the maker of that sized sheet, now commonly employed for business, having used the device of cap and bells. Paper is now made more uniformly of the same size, and receives particular denominations, as foolscap, post, demy, &c.; drawing paper has also similar denominations, depending on its size, as stated below.

A duty was first laid on paper by Statute 10 Anne, c. 19: and, after undergoing various changes, it was fixed, in 1803, on the footing on which it stands at present, but an alteration is at this time under the contemplation of the Government. By the Statute 43 George III. c. 69, it is enacted that

£. s. d.

For every pound weight avoirdupois of paper made in Great Britain, (the duties in Ireland have long been identical or nearly so with those in Britain,) of the first class or denomination, that is to say, all paper, other than brown paper, made of old ropes or cordage only, without extracting the pitch or tar, or any part therefrom, and without any mixture of other materials therewith, and not being glazed paper for clothiers and hot-pressers, or sheathing paper, or button paper, or button board. . . 0 0 3

For every pound weight avoirdupois of paper made in Great Britain, of the second class or denomination, that is to say, all brown paper made of old ropes, as afore said 0 0 1 $\frac{1}{2}$

Pasteboard and millboard are charged with the duty by the hundred weight as follows:

All pasteboard made from paper of the first class 1 8 0

Pasteboard made from paper of the second class 0 14 0

Millboard, sheathing paper, glazed paper for clothiers and hot-pressers, button paper, and button board 1 1 0

All coloured, printed, or stained paper is also charged with a duty of 1 $\frac{3}{4}$ d. per square yard over and above the duty of 3d. per pound charged on such paper in its plain state.

The following Table shows the annual duty on paper, rags, &c from 1820 to 1831.

Report on the paper duties.

(1073.) The policy of these duties on paper has been much questioned, and a Report has recently been made by the Commissioners of Excise Inquiry, and the following abstract of this Report by the Secretary of the Board contains certainly many important remarks. English-made paper was first charged, as above stated, with duty in 1711, the 10 Anne, c. 19.

"The duties on paper were first levied in Ireland by the 38 Geo. III. c. 5, and were charged by a rate on the machinery employed in the manufacture. They were assimilated to the duties in Great Britain by the 5 Geo. IV. c. 55.

"The gross receipt of duty in 1834 was £833,822 12s. 4d., the net receipt £771,162 13s., from which latter sum the charges of the collection are to be deducted.

"A drawback of the whole duty is allowed on all paper made in the United Kingdom on exportation; and by the 43 Geo. III. c. 69, and 5 Geo. IV. c. 55, allowances of duty were granted to clothiers, hot-pressers, and to the Universities, which amounted, with the drawback in 1834, to £62,659 19s. 4d.

"A licence duty of £4 is charged on all manufacturers of paper.

"The Commissioners advert to the important advantage which is enjoyed by the paper-makers under these regulations, viz., that, unlike other growing duty traders, they have 'the process of their manufacture exempt from Excise interference,' to which exemption the Commissioners attribute 'the very great progress which has been made in the application of various improvements to this manufacture, especially those arising from the extensive introduction of machinery, which have enabled the manufacturers, by combining the two processes of making and drying the paper through the operation of large cylinders heated by steam, to complete in a few minutes a quantity of paper which formerly occupied a period of as many weeks.'"

"Injurious effects of the separation of paper into two classes.—The separation of paper into two classes by the 43 Geo. III. c. 69, with two rates of duty, appears, from the concurrent testimony of almost all the witnesses examined upon the point, to be attended with the most injurious effects. This separation was effected by the 43 Geo. III. c. 69, by which it was enacted that all paper and pasteboard should be considered first

class, and subject to 3d. per pound duty, unless made wholly out of old tarred rope and cordage, without extracting therefrom the pitch, or tar, or any part thereof, and without any mixture of other materials therewith.

"It appears from the evidence of Mr. Dickinson, the chairman of the deputation of London paper-makers, and himself an eminent and extensive manufacturer, as well as from that of Mr. Gater and Mr. Gaussen, also considerable manufacturers, and which is confirmed by the deputation of paper makers at Glasgow,—

"1st. That old tarred rope, which during the war, and before chain-cables came into use, was worth £4 to £5, or less, is now worth £11 to £12 per ton.

"2dly. That while old tarred rope has so much increased in price, some sorts of first-class materials have so much declined in value as to be worth only £3 10s. to £4 per ton.

"3dly. That it has been found practicable, without extracting the pitch or tar of the old rope, completely to neutralize the smell of it; the result of all which is that that which, at the time the law was settled, formed a good practical distinction between first and second class papers, has long ceased to be so; and that a very extensive evasion of the law, by the use of first class materials in second-class paper, is the consequence.

"The department of Excise acknowledge that frequent complaints and disputes arise upon the subject; that it is difficult to distinguish between the two; and that one rate of duty would be infinitely preferable to two.

"It is almost superfluous to add, that the continuance of the present classification is condemned by the Commissioners of Inquiry, as calculated to produce consequences highly injurious both to the manufacturer and to the revenue."

"Injurious effects of the high duty on the first class paper.—The injurious effects produced by the present high rate of duty on first-class paper is the next point adverted to; in reference to which, in consequence of the decline which has taken place in the price of paper, the rate of duty is described as amounting now to double what it was, and as forming a great check on the consumption of paper, as well as a great inducement to avoid paying the duty; the rate of profit therefore to the manufacturer has been reduced so low, by the competition with the smuggler, that a very large proportion of the capital vested in mills and machinery is represented as affording no return. On the inferior descriptions of wrapping paper the rate of duty is stated to be not less than 200 per cent., and on the finer sorts, such as printing paper, it is fifty per cent.

"The frauds on paper in Ireland are stated by Mr. Saurin, the Solicitor for Ireland, and by Mr. Plunkett, the Inspector of the Revenue Police, and Mr. Ryan, the Collector for Londonderry, to exist to an enormous amount.

"The prejudicial effect of the high duty in reference to paper used in the printing of books is forcibly demonstrated by the Commissioners of Inquiry, and is illustrated by reference to Mr. M'Culloch's *Commercial Dictionary*, and to the evidence of Messrs. Knight and Parker, the publishers of the *Penny* and *Saturday Magazines*.

"The demand for books is stated to be so extremely uncertain, that in a case where a publisher calculates, from the best information, the probable sale of 1000

Mechanical Processes.

Manufac-
tures.

copies of a Work, he perhaps does not sell 500 copies, or even so many as 250 copies. The duty, however, has been paid on the whole 1000 copies, and therefore adds materially to the loss resulting from the speculation.

"The duty on the paper employed in a Work such as the *Penny Cyclopædia* is estimated by Mr. Knight at one-fifth of the whole; and he states that such a speculation, which now pays at 50,000 copies, would, if the duty were reduced one-half, pay at 40,000 copies, and, if entirely repealed, at 30,000 copies.

"Mr. Knight further expresses his opinion, that a considerable reduction of the paper duty would call numerous such works into existence.

"The operation of the duty on the ordinary volume is estimated by the London deputation at from 1s. to 2s. 8d. a volume, according to the sale.

"The proportion of paper used in printing is estimated as exceeding two-thirds of the whole.

"The Commissioners of Inquiry justly observe, therefore, 'that a large reduction of duty will be materially felt, precisely in that branch of the manufacture to which it is desirable that relief should be afforded.'

"The effect of the repeal of the duty on almanacs, which amounted to 1s. 3d. on each almanac, is very remarkable. No less than 200 new ones are described as having immediately started, of some of which upwards of 250,000 copies were sold within a short period, although the old ones maintain their ground; and Moore's Almanac is stated this year (1834) to have actually doubled its former sales.

"The result of the evidence received, and the observations of the Commissioners of Inquiry in the several parts of the United Kingdom, is stated by them to be 'that the duties, at their present rate and mode of charge, have a most injurious tendency, both in creating temptations to evade the law, and also in checking the consumption of an article which would otherwise be in demand for all classes of the people.'

"As a remedy for these evils,' the Commissioners recommend 'that the present division of paper into two classes should cease, and that so long as that manufacture shall continue subject to an Excise duty, such duty shall be levied at an uniform rate; and that the present rate of first-class paper should be reduced one-half, and accordingly that 1½d. per pound should be fixed as the whole amount to be levied on paper of all descriptions;' and further, that the present separate classes of paste-board should in like manner be consolidated and reduced, and subject to one duty of 14s. per cwt., that rate of duty to be also payable on millboards and other boards, which now pay a duty of £1 1s. per hundred-weight.

"The manufacturers calculate that a very small loss of revenue will result from these measures. The net produce of the duty on first and second-class papers, in 1834, was £718,043, from which, if the duty on second-class paper be deducted, viz. £101,023, there will remain £617,020. Mr. Gaussen calculates that not more than £150,000 of the above sum would be lost in the first year, and that every year afterwards that loss would become less. The London deputation estimate the 'amount which would be received by the Excise, after the consolidation of the duties on first and second-class paper, at £680,000,' leaving a loss of revenue of only £62,980.

"The Commissioners of Inquiry advert to a complaint which appears to have been made by the deputations of

paper-makers both in Edinburgh and Glasgow, of the loss and inconvenience arising from missing opportunities of conveyance, to which they are frequently subjected by the regulation which requires them to retain their paper on the premises for twenty-four hours after the departure of the officer who had weighed it and charged it with duty. The English manufacturers, as well as the officers of Excise, are opposed to the alteration of this regulation, on the ground 'that a shortening of the period would open a door to evasion of duty.'

"The Commissioners of Inquiry consider it inexpedient to dispense with this regulation during the continuance of the present rate of duty; but in deference to the 'strong feeling which the whole of the Scotch manufacturers have expressed upon the subject,' they suggest that 'some relaxation as to time may be allowed as soon as the duties are reduced and consolidated into one.'

"Penalties.—The Commissioners of Inquiry recommend a revision and reduction of the whole of the penalties established by the laws relating to paper, upon the grounds that 'the original penalties in the Act of Anne, establishing the duty, in no case exceeded £50, and were generally very much below it;' and that enormous penalties do not and will not check smuggling, so long as the temptation afforded by high duties exists.' The Commissioners specially allude to one penalty of £200, which is inflicted by the 1 Geo. IV. c. 58, sec. 6, for every label delivered to the manufacturer by the Excise, for which he cannot account. The utmost loss of revenue consequent upon the loss or misuse of the label being the amount payable upon one ream of paper, which, in the case of writing and printing paper, would be from 5s. to 6s. 3d., and on a ream of millboard 25s. The Commissioners suggest that a penalty of 40s., or at most £5, would be quite sufficient to prevent fraud on this point.

MISCELLANEOUS MECHANICAL PROCESSES.

We have endeavoured to classify, as far as possible, the several mechanical processes described under this part of our Treatise, and to reduce them into something like their natural order. The two principal divisions are now completed, i. e. mechanical processes on metals, and the manufacture of fibrous materials. Others which fall under neither of these heads will form the subject of this third and last section, and, being of a very miscellaneous nature, they are collected and given under the above title.

Printing.

(1074.) Under this head we shall confine our remarks and description to the Art of printing from movable types, by the common press and by machinery, and stereotype printing; but in the two following articles we shall endeavour to illustrate the nature of copper-plate printing and lithographic printing. Printing linen, cotton, &c., is already described, (Art. 774, *et seq.*)

The Art of printing in Europe is comparatively a modern invention; it has not at least been known for more than four hundred years; but it appears that printing was practised in China nearly two thousand years back, although not with movable types. This, therefore, would hardly seem to claim our attention in this article, according to the meaning we have affixed

Printing in
China.

Mechanical
Processes.

Manufac-
tures.

to the term printing; but as it was employed in the printing books, &c., it may, perhaps, be with some propriety slightly described in this place, particularly as it remains in the same form in use amongst them to the present day. Their process is as follows. They take blocks of wood, firm, close, and smooth, of the form and size of the page they mean to print, on the one side they glue a paper, on which some able penman delineates the necessary letters and characters; the wood in this state is put into the hands of a sculptor, or rather wood engraver, who, following with proper tools the outlines of the characters inscribed on the paper, cuts out the other parts, leaving the letters in relief; the paper then is gently removed, and the engraved tablet thus prepared is that by which their printing is executed. The disadvantages of this mode of execution are manifest, as there must be as many blocks as there are pages in a book, and they are of course useless in printing any other Work; besides, the process is extremely tedious and expensive. The Chinese Chronicles state that this mode of printing was discovered in China about fifty years before the commencement of the Christian Era, and we have seen (Art. 1065.) that the manufacture of paper was first introduced by them about ninety-five years after the same; so that printing amongst these people preceded paper-making about one hundred and forty-five years, during which period they printed on silk cut into leaves of proper dimensions.

It may be remarked that, to counterbalance in some measure the disadvantages of this method of printing, the Chinese books are free from any errors of the press, are very accurate, and extremely beautiful, the best penmen only being employed for this business; but, on the other hand, both their paper and ink are bad, so that a very old book is seldom to be met with in China.

(1075.) From what has been said, it appears that the Chinese process is rather a species of printing from plates than from types, and whether we derived our Art of wood-engraving and printing from them or not it is now difficult to say; but we certainly did possess that Art before the use of types was known; playing cards, for the amusement of Charles VI. of France, having been thus printed during the latter part of the XIVth Century, whereas the discovery of the Art of printing by types was not made before the XVth Century. To the impression for cards succeeded various devices and characters, with some lettered descriptions, printed only on one side, but which, by afterwards pasting the blank sides together, formed a kind of book; of these first Works, it is believed, some still exist. It appears that in Earl Spencer's library is a specimen of this kind of printing as early as the year 1443.

Great controversy has been carried on respecting the author or inventor of the present Art of printing; but as this question has been examined at considerable length in our alphabetical division, it will not be necessary for us to recur to it in this place; we shall therefore simply observe, in reference to the mechanical improvements in the Art, that it is now about 300 years since the publication of the first Bible, and from that time to about the commencement of the present century no new principle was introduced. That there was a general advance in the neatness of execution and in the taste with which successive Works were got up, is not denied, but the principle remained the same; so also in the form of the press, a lightness and elegance of struc-

ture succeeded to the ponderous and shapeless German press, paintings and engravings of which are sometimes to be met with; still, however, its principle of action remained unchanged, as well as the method of inking the type, on the accuracy of which latter process the great beauty of modern printing, in comparison with the old, consists, and the difference is very striking.

"The early printers were frequently governed by the wish to make their printed pages bear a resemblance to the old manuscript books formerly in use; and upon the whole much less taste was displayed, in respect of neatness and accuracy, than might have been expected from the intelligent class of men who first cultivated the "divine art." The following particulars relative to the early productions of the press will show how the style of book-printing was gradually improved: "With respect to their forms, they were generally either large or small folios, or at least quartos: the lesser sizes were not in use. The leaves were without running title, direction-word, number of pages, and divisions into paragraphs. The character itself was a rude old Gothic mixed with Secretary, designed on purpose to imitate the handwriting of those times, the words were printed so close to each other that they were read with difficulty, even by those who were used to manuscripts and to this kind of letter, and often led the inattentive reader into mistakes. Their orthography was various, and often arbitrary, disregarding method. They had very frequent abbreviations, which in time grew so numerous and difficult to be understood that there was a necessity of writing a book to teach the manner of reading them. Their periods were distinguished by no other points than the double or single one, that is, the colon and full point; but afterwards was introduced an oblique stroke, thus /, which answered the purpose of our comma. They used no capital letters to begin a sentence, nor for proper names of men or places. They left blanks for the places of titles, initial letters, and other ornaments, in order to have them supplied by the illuminators, whose ingenious Art, though in vogue before, and at that time, did not long survive the masterly improvements made by the printers in this branch of their business. Those ornaments were exquisitely fine, and curiously variegated with the most beautiful colours, and even with gold and silver; the margins, likewise, were frequently charged with variety of figures of saints, birds, beasts, monsters, flowers, &c., which had sometimes relation to the contents of the page, though often none at all. These embellishments were very costly; but for those that could not afford a great price, there were more inferior ornaments, which could be done at a much cheaper rate. The name of the printer, place of his residence &c. were either wholly neglected, or put at the end of the book, with some pious ejaculation or doxology. The date was likewise omitted, or involved in some cramped, circumstantial period, or printed either at full length, or by numerical letters, and sometimes partly one and partly the other; thus one thousand CCCC and lxxiii, &c.; but all of them at the end of the book. There was no variety of characters, no intermixture of Roman and Italic, which are of later invention, but the pages were continued in a Gothic letter of the same size throughout. They printed but few copies at once, for 200 or 300 were then esteemed a large impression; though, upon the encouragement received from the learned, they increased their numbers in proportion."

Mechanical
Processes.

First print-
ing in Eu-
rope with
blocks.

Recent im-
provements
in printing.

Manufactures.

"About 1469-70, alphabetical tables of the first words of each chapter were introduced as a guide to the binder. Catch-words (now generally abolished) were first used at Venice, by Vindeline de Spire. Early printed books had no signatures. Signatures are those letters of the alphabet which are put at the bottom of the right-hand pages of sheets to distinguish their order. When the alphabet is finished, a second begins A a, or 2 A, instead of a single A; and when that is terminated, A a a, or 3 A, begin the third, and so on. In order to indicate more correctly the order of each sheet, printers add figures to the initial letter on the third, fifth, and seventh pages; the numbers of these figures, which do not pass the middle of the sheet, point out the size of the edition. Thus, A 2 on the third page, A 3 on the fifth, and A 4 on the seventh, show a work to be in 8vo.; in the 12mo. size, A 5 on the ninth page, and A 6 on the eleventh page, &c.; but it is now customary to give signatures only on the first and third pages of 8vo., and on the first, third, and fifth pages of 12mo."

In some modern French Works, figures are substituted for letters, and the other leaves are marked by asterisks. The invention of signatures is ascribed by M. Marolles to John of Cologne, who printed at Venice in 1474; the Abbé Rive attributes it to John Koelhof, a printer at Cologne, and contemporary with the former, from whom we have a Work of an earlier date. It is, however, of little consequence who was the inventor, for, on the whole, signatures are rather a clumsy expedient, merely to direct the binder in folding the sheet, and are generally much too conspicuous upon the pages.

One of the chief improvements in the style of typography has been the dismissal of abbreviations and connected letters from the founts. Formerly abbreviations were very common, the word *they* was indicated by the letter *y* and a small *e* above it: the conjunction *and* was indicated by &, which is a contraction of *et*. There were many of this species of abbreviations in printing both the English and Latin languages, and these were not more unseemly than the connected letters; such, for instance, as the junction of the letters *c* and *t* by a curve stroke from the top of one to the other. In recent times, all these connected letters have been disused, with the exception of *ff* and *fl*, and these are only continued because the head of the common *f* would press against the *l*, and be broken. Another very great improvement has been effected in the dismissal of the long *s*, in case of two of this letter coming together.

Printing machines.

It is not, however, merely in matters of taste that printing has been improved, the mode of operation has been in many cases superseded. All our manufactures and machinery have, during the present century, made a great advance, of which we have had frequent occasion to speak in the course of the present Treatise, and that of the printing press has not been neglected.

The great and general increase of education and spirit of inquiry which had spread amongst the English called for some more prompt means than the old press afforded for expediting the news of the day, and this was no sooner felt than it was supplied by the invention of the printing machine, which produced copy after copy to almost any extent. Of these machines we shall speak more in detail in a subsequent part of this article after describing the usual process; they are merely referred to here as an important feature in the printing Art. Still,

however, these machines, powerful as they were, were not all that the state of English society required. To increase their speed of production two or more such machines must be worked, and other copies in type must be set up, which required either a greater time or an increased number of hands. This led to the Art of stereotyping; that is, one complete copy of the paper being set up, an impression is immediately taken from this in plaster to form a matrix in which as many copies may be made as the urgency of the business requires, and as many machines put in action. This method will also be described more at length in a subsequent page. It has, perhaps, brought the Art of printing to its greatest possible perfection.

(1076.) *Process of printing.*—We have hitherto attended only to the early progress of this important Art; it remains for us now to give some description of the several operations. Under Art. 929. is given an account of type founding; we are therefore now to suppose that types are already provided for the printer's use. Each individual class, viz. of letters, points, &c., being of the same height, and distinguished from letters of another class by one or more nicks or notches, which range evenly when the types are set, which, as we shall see, is very convenient in guiding the compositor. There are, in the present day, a great variety of sizes for types to the extent perhaps of forty or fifty, enlarging by a progressive scale from the most minute used in printing pocket Bibles to the largest seen in posting-bills in the streets. Many of these have a distinct name; the smallest is called *diamond*, then follow in gradation upwards, *pearl*, *ruby*, *nonpareil*, *minion*, *brevier*, *bourgeois*, *long primer*, *small pica*, *pica*, and *english*; the larger sizes generally take their names thus, *two line pica*, *two line english*, *four*, *six*, *eight*, or *ten line pica*, &c. Other nations have adopted different designations for their letters, principally from the names of their inventors. All kinds of types are sold by the founders at a price per pound varying in amount with the size of the letter; the smallest size, diamond, costing about 12s. per pound, brevier about 3s. 6d., English 2s., and so in proportion for all intermediate sizes. These prices may appear great, but when it is known that in the diamond size 2800 go to the pound in the letter *i*, and of the thinnest space about 5000, they will not be considered exorbitant.

A complete assortment of types is called a *fount*, which may be regulated to any extent. Every type-founder has a scale, showing the proportional number of each letter required for a fount; but it may be observed that every language requires a particular scale. For the English language, the following is a type-founder's scale for the small letters of a fount, of a particular size and weight, viz.

a	8,500	j	400	s	8,000
b	1,600	k	800	t	9,000
c	3,000	l	4,000	u	3,400
d	4,400	m	3,000	v	1,200
e	12,000	n	8,000	w	2,000
f	2,500	o	8,000	x	400
g	1,700	p	1,700	y	2,000
h	6,400	q	500	z	200
i	8,000	r	6,200		

It will be seen from this scale that the letter *e* is used much more frequently than any other letter. The English type is said to be at present superior in point of neatness

Mechanical Processes.

Different kinds of types.

Manufac-
tures.

and elegance of form to those of any other Country. For this characteristic they have been much indebted to William Caslon, who was originally an engraver of ornamental devices on the barrels of fire-arms and on bookbinders' tools. The neatness with which he executed these works brought him into notice, and he made his first essay as a letter-founder in forming an alphabet of Arabic letters for an edition of the New Testament, about the year 1720. Before that time, the types used in England had been mostly imported from Holland; but the decided superiority of Caslon's letters over those of all competitors, at home and abroad, soon put a stop to the importation of foreign types, instead of which the English types were now exported to several Continental States.

Composing.

(1077.) *Composing*.—All the types in use in the different printing-offices are sorted in cases or shallow boxes with divisions; there are two kinds of cases, the upper and the lower case, the latter lying nearest to the compositor upon the frame for their support. In the upper case are placed all the capitals, small capitals, accented letters, figures, and characters used as references to notes. In the lower case lie all the small letters, points, and spaces to place between the words. In the lower case no alphabetical arrangement is preserved, the letters having merely a larger or smaller box allotted to them, according as they are more or less frequently required, and all those letters most in request are placed at the nearest convenient distance to the compositor. By this ingenious but irregular division of the lower case much time in composing is saved, the operator requiring no label to direct him to the spot where the particular letter which he wants is to be found. To a stranger in a printing-office nothing appears more remarkable than the rapidity with which the compositor does his work, constant practice very soon leading the hand rapidly and mechanically to the letter required. When italic letters are to be introduced, they are taken from a separate pair of cases from the same fount.

The process of composing and forming types into pages has been slightly noticed in the alphabetical division of this Work; it is proposed here to explain it more particularly. Placing the copy or manuscript before him on the upper case, and standing in front of the lower case, the compositor holds in his left hand what is called the composing-stick. Sometimes this instrument is of wood, with a certain space cut in it of the particular width of a line or column; but more commonly it is made of iron or brass, with a movable side which, by means of a screw, may be regulated to any width of line. In either case the composing-stick is made perfectly true and square. One by one the compositor lifts and puts the letters of each word and sentence, and appropriate points, into his stick, securing each with the thumb of his left hand, and placing them side by side from left to right along the line. When he places a letter in the stick, he does not require to look whether he is placing it with the face in its proper position, this object being accomplished by looking at what is called the *nick*, which must be placed outwards in his composing-stick. This is one of those ingenious contrivances for saving labour which experience has introduced into every Art, and which are as valuable for diminishing the cost of production as the more elaborate inventions of machinery. When he arrives at the end of his line, the compositor has a task to perform in which the carefulness of the workman is greatly exhibited; for

it is requisite that the first letter and the last must be at the extremities of the line, as there must not be spaces left in some instances, and crowding in others, which would frequently occur without great care. Each metal type is of a constant thickness, so far as regards that particular letter, though all the letters are not of the same thickness, and the adjustments, therefore, to complete the line with a word, or at any rate with a syllable, must be made by varying the thickness of the spaces between each word. A good compositor is distinguished by uniformity of spacing; he will not allow the words to be very close together in some instances, and with a large gap between them in others, his duty being to equalize the spacing as much as he possibly can, which is in some cases very troublesome. In composing poetry, or similar matter, where there is always a blank space at one of the ends of the line, spacing is very easily accomplished by filling up the blank with larger spaces, or *quadrats*. Still, however, whether prose or poetry, the matter of each line must be equally adjusted and *justified*, so as to correspond in point of compactness with the previously set lines. The process of composing is greatly facilitated by the compositor using a thin slip of brass, called a *setting-rule*, which he places in the composing-stick when he begins, and which, on a line being completed, he pulls out and places upon the front of the line so completed, in order that the types he sets may not come in contact with the types behind them, and may smoothly glide into their places to the bottom of the composing-stick.

When the workman has set up as many lines as his composing-stick will conveniently hold, he places them on an elongated board, with a ledge on one or perhaps both sides, termed a *galley*, by grasping them with the fingers of each hand, and thus taking them up as if they were a solid piece of metal; and the facility with which some compositors can lift what is called a *handful* of movable type without deranging a single letter is very remarkable. This sort of skill can only be attained by practice; and one of the severest mortifications which the printer's apprentice has to endure is to toil for an hour in picking up about a thousand letters, and then to see the fabric destroyed by his own unskilfulness, leaving him to mourn over his heap of broken type, technically called *pie*.

Letter by letter, and word by word, is the composing-stick filled, and by the same progression the galley is filled by the contents of successive sticks. When the compositor has set up as many lines as fill a page, he binds them tightly round with cord, and removes them from the galley, and sometimes, as in the case of newspaper and similar work, the *handfuls* of type are accumulated till they fill the galley, and are then removed in long columns. After the matter is thus so far prepared, it is the duty of the compositor to take an impression or *first proof* from the types, and to correct the errors he may have made; these proofs are usually taken by means of an old large press kept for the purpose. This is not, however, always done, the proofs of galleys and pages being sometimes taken by a small iron roller, which runs on raised ledges upon a neat metal table, on which the types are placed, giving a sufficient impression to the compositor without any trouble. After the galley matter is corrected and recorrected by the compositor, it is divided into pages of the size wanted; and head-lines, or figures indicating their number, being added, the pages are arranged upon a large firm table, and there

Mechanical
Processes.

Manufac-
tures.

securely fixed up in an iron frame or *chess*, by means of slips of wood and wedges, or *quoins*.

This process, which is called *imposing*, being completed, and the face of the types being levelled by a *plainer* and mallet, the *form*, as it is called, is proved and prepared for press; proof-sheets are now taken, and subjected to the scrutiny both of a *reader*, employed in this peculiar function in the office, and of the author. These having made their marks pointing out words and letters to be altered or corrected, the compositor once more goes over the form, correcting the errors by lifting out the letters with a bodkin, and, when revised, the sheet is pronounced ready for working. It should be mentioned that the imposing table, at which all these corrections are made is composed of smooth stone or marble, on the top, from the circumstance of materials of that nature not being liable to rust from the water which is often thrown upon the types while preparing them for the press, or in laying them out for distribution after working off.

It is unnecessary to state that the size of books greatly varies; but the sizes are all reducible to a standard determined by the number of leaves into which a sheet of paper is folded. The most common size is *octavo*, each sheet of which contains eight leaves, or sixteen pages; the next is *duodecimo*, containing twelve leaves, or twenty-four pages in the sheet; and the next *octodecimo*, or eighteens, containing thirty-six pages in a sheet. There are many other sizes, such as the *quarto*, the smaller *twenty-fours*, &c. The knowledge of placing pages of types in a form so as to produce, when printed, a regular series upon paper, is one of the branches of the Art to be acquired by the young compositor.

Printing
presses.

(1078.) *Printing press*.—We come now to the description of the printing press, and the methods followed in the usual process of printing. The forms being duly composed in the composing-room are carried to the press-room, and are placed under the charge of the pressman.

The earliest printing presses were exceedingly rude, and seem to have resembled the common screw press, with a contrivance for running the form under the point of pressure, an operation which must have been laborious, slow, and exceedingly defective, from the difficulty of regulating the impression; it also endangered the face of the types. The defects in these original presses were at length remedied by an ingenious Dutch mechanic, Willem Jansen Blaew, who carried on the business of a mathematical instrument maker at Amsterdam; he contrived a press in which the carriage holding the form was run below the point of pressure, which pressure was given by moving a handle attached to a screw hanging in a beam having a spring, which caused the screw to fly back as soon as the impression was given. This species of press, which was almost entirely formed of wood, continued in general use in every Country in Europe till the beginning of the present century.

Common
printing
press.
Pl. lxxx.
Fig. 1.

The modern common press is represented in plate lxxx. fig. 1, in which A, A represent two cheeks or strong vertical iron sides, bound together by four horizontal bars; the first of these, B, is called the cap, and merely keeps the posts at a proper distance; the second cross bar C, called the *head*, is fitted by tenons at the ends into the mortises between the cheeks, and the bar admits of a small motion or play in consequence of the mortises being filled up with pieces of pasteboard or

soft wood; the head C is suspended from the cap B by two strong screw bolts *s, s*, and in the centre of it is fixed, by two short bolts, a brass nut, containing a female screw or worm for receiving the upper end of the great vertical spindle or screw S, by which the pressure is produced; the third bar D, called the *shelf* or *till*, is intended to guide and keep steady a part called the *hose*, which contains the spindle and screw; the next cross bar E, called the *winter*, is placed between the cheeks, in order to support the carriage, and it sustains the effort of the press below in the same manner as the head does above. The spindle or screw F F is a strong vertical bar of iron terminated at the lower end with steel; its upper end is formed into a small screw which works in the small brass nut of the head; and in the eye of the spindle, a little below its upper end, is fixed the crooked bar or handle H, by which the press is wrought.

Beneath the lower end of the spindle is placed the *plattin* G G, or the body which gives the pressure to the paper. It is suspended from the point of the spindle by the *hose*, a square frame or block of wood, shown at K, which is guided by passing through the shelves. The lower end of the spindle passes through the hose, and rests by its point in the plug, fixed in a brass pan supplied with oil, which is again fixed to an iron plate let into the top of the plattin; when the pressman, therefore, pulls the handle H he turns the spindle, the round of which moves in its screw box, and, descending, brings down the plattin, which thus presses upon the paper lying above the types. The plattin is suspended from the spindle and rises up again with it by means of a garter or fillet of iron screwed to the hose, and entering into a groove round the upper end of the spindle; the plattin is hung truly level by four threads passing from its four corners to the four corners of the lower part of the hose.

The next important part of the printing press is the *carriage* L L, the object of which is to bear the types and carry them below the plattin. The carriage is supported on a horizontal wooden frame, the fore part of which is sometimes sustained by a *forestay*, while the back part rests on the winter. Beneath the plank of the carriage, *cramp irons*, or short pieces of iron and steel, are nailed, which slide upon two long iron bars or ribs, fixed upon the upper part of the horizontal wooden frame. In order to run the carriage in and out upon the wooden frame, there is placed beneath the carriage the *split* or small spindle, having a double wheel on the middle of it, round which leather belts are fastened, the opposite end of the belt being nailed to each end of the plank of the carriage. On one of the ends of the split is fixed the winch or handle *n*, by turning which the pressman can run the carriage in and out below the plattin at his pleasure. The carriage consists of a strong wooden plank, on which is fixed a square wooden frame, forming the cell, in which a polished stone is placed to sustain the form or frame of types. Stay belts of leather are fixed to this cell by one end, and by the other to the cheeks of the press, so as to prevent the carriage from running out too far when drawn from under the platform. On the outer end of the plank is fixed the *gallows* M, which sustains the tympan when they are turned up to receive a new sheet of paper. These tympan, shown at N N, are light square frames covered with parchment. They consist of three slips of thin wood with a *headband* or top slip of thin iron. The two tympan are so constructed that the one is

Mechanical
Processes.

Manufac-
tures.

small enough to lie within the other, and the other and the exterior one is fitted by iron hinges to the cell; two or three folds of blankets are placed between the two tympana to equalize the pressure of the platin upon the surface of the types. A square frame of very thin iron, called the *frisket*, is fastened by hinges to the head-band of the exterior tympan. It is made to fall down upon the tympan, to enclose the sheet of paper between them, and the frisket is covered with a sheet of paper or parchment which is cut out so that the sheet when placed between the tympan and frisket and folded down together on the form of types may receive the ink from the surface of the types, while the frisket sheet preserves the margin from being soiled. When the tympan and frisket are thus folded down, they lie flat on the form of types, the carriage containing them is then run beneath the platin, so that, when the handle *H* is pulled, the platin presses upon one-half of the form of types; the carriage is then run further in beneath the platin to press upon the other half of the form of types. In this way the impression of the types is made upon the paper by two separate pulls; by turning the winch *n* the carriage is withdrawn from beneath the platin, and the tympan on being lifted up round its hinges rests obliquely against the galleys. The frisket is then lifted up on its hinges, and supported by a slip of wood descending from the ceiling till the printed sheet is taken out and a clean one put in.

Subsequent
forms of
press.

It has been already stated that scarcely any improvement, except in the neatness and firmness of the workmanship, was made in printing presses from a very early period of the invention to the commencement of the present century, about which time several new presses were proposed. Of these, the Apollo press, Prosser's press, Roworth's press, and the Stanhope press were the most important, particularly the latter. The impression by the common press being taken, as we have described, at two successive pulls, a part of the middle of each sheet receives two separate pressures, the effect of which is necessarily to diminish the uniformity of the impression on the paper, besides which, a great deal of time is wasted by having to give two separate pulls, so that it was very desirable to have such a change made in the old kind of press as to have the platin of sufficient size to effect the whole impression at once, or by a single pull only. The first invention of this kind was the Apollo press, imported into this Country from France. In this the platin was made of iron instead of wood, and its surface was large enough to print the whole sheet; the lower surface of the plate, which was of brass, was ground perfectly flat, and was of such thickness as not to bend nor yield at the parts most distant from the centre of pressure. The spindle was joined by connecting rods to a long lever placed by the side of the press, which was wrought by the pressman with both hands, in a vertical plane, like the handle of a pump; these presses, however, were worked only with great labour, and fell into disuse.

Apollo
press.

Roworth's press.—This is considered by some to have been the first really improved form of press after that described above as the common press. Here the spindle, instead of being furnished with a screw, is entirely plain, and has its upper extremity turned to a smooth cylinder, which works in a socket fitted into the head of the press; on the upper end of the spindle, immediately below the head, a short cross arm of hardened steel is fixed, the polished surface of which acts against a circular inclined

plane, also of polished and hardened steel, which, being actually a part of a screw, causes the spindle to descend. This inclined plane has different inclinations at different parts; at first the inclination is great, so that at the beginning of the pull the descent of the platin is rapid, but when it has approached near to the tympan, and, consequently, when the force is really required, the inclination of the plane is very slight, so as to produce the greatest mechanical effect.

Mechanical
Processes.

The next important improvement in printing presses was by the late Lord Stanhope, the machine being called after its inventor the Stanhope press; since which other forms have been proposed by Mr. Ruthven of Edinburgh; by Mr. George Clymer, called the Columbian press, being an American invention; Barclay's American press; Wells's press; and some others, which, however, we cannot undertake to describe in this article. We shall, therefore, refer only to the first two of these, viz.

(1079.) *The Stanhope press.*—This is represented in Stanhope pl. lxxx. fig. 2, 3, in which *A A* is the body of the press; this being a heavy cast-iron frame formed in one piece, which rests upon a wooden cross *B B C*, to which it is firmly screwed down. Two horizontal rails *D, D* are screwed, at *b, b*, fig. 3, to two projecting pieces cast all in one with the body of the press, in order to sustain the carriage when the pull is made. The ribs of the carriage are made to slide in grooves formed along the upper surface of these rails, and are moved by the handle *m*, with a split and leather belts resembling those in the common press. A brass nut or female screw is fixed in the upper part *d* of the body of the press, in which the upper end of the spindle works; the principal improvement of Lord Stanhope's press consists in his manner of giving the descending motion to the screw. The press is worked by a handle *H*, which is firmly fixed into the lower end of the vertical bar *M*, the lower point of which moves in a hole in the main frame, and the upper end passes at the same time through a collar in the projecting piece *c*; having passed through this collar, the end of the bar *M* joins a short lever *N*, which is again connected by the link *O* with another short lever *P*, fixed upon the upper end of the screw. The pressman, in pulling the handle *H*, turns round the spindle *M*, and, by its connection with the rod *O*, &c., the great lever turns with it and causes the platin to descend and produce the requisite pressure; the power of the lever *H* is, however, transmitted to the screw, in order to proportionate the effect required at the different parts of the pull. At the commencement of the pull, for instance, when motion only is wanted, the handle *H* lies in a direction parallel to the frame across the press, and the short lever *N*, which is nearly perpendicular to it, is likewise perpendicular to the connecting rod *O*; but the lever *P* of the screw makes a considerable angle with *O*, and it then acts by a spindle radius to turn the screw; when, therefore, the lever *H* begins to pull, the lever *N* acts with its full power upon another shorter length of lever on *P*, so that the screw will be turned more rapidly than if the link *O* were attached to it; the pull being continued, the situation of the lever changes, the length of *P* always increasing in its actual length from its coming nearer to a perpendicular to *O*, and the acting length of *N* diminishing, because by the obliquity of the lever the link approaches the centre. The handle *H* comes now into a more favourable position for the pull, as the

Stanhope
press.
Fig. 2, 3

Manufac-
tures.

pressman finally pulls in a direction nearly at right angles to its length; by this means the plattin is at first brought quickly down upon the paper where motion only is required; but as the levers are gradually coming into the most favourable position for exerting the greatest force, this maximum pressure is produced just at the moment when it is wanted, *viz.* when the plattin touches the paper to be printed. The range of the handle is limited by a stop, which is movable to a small extent, in order to vary the pressure for different kinds of work; the form of types, instead of resting upon a stone, lies upon a cast-iron block, which has its upper surface ground perfectly flat, and placed quite in a horizontal position. The size of the Stanhope press allows of a whole sheet being printed at one pull.

In some of these presses a variation of power is obtained by a screw adjustment at the end of the link O, as shown in the figure, by which it can be shortened. It is done by fitting the centre pin, which unites it to the lever P in a bearing place, and slides in a groove formed on the side regulated by the screw; thus the descent of the plattin may be increased or diminished, and its surface is turned so as to be perfectly plane. Since the invention of this press various improvements have been made upon it; one by M. de Heine has been secured by a Patent. In this the screw has been avoided by a spiral or curved inclined plane fixed on the head of the press. On the upper end of the spindle a cross arm is placed, which acts against a fixed inclined plane, and thus performs the functions of the screw; this substitute has its advantage by allowing the acting faces to be made of hardened steel. Mr. Peter Keir also made several valuable improvements on the Stanhope press: the slider *d* in this being formed by boring out a cylindrical hole down the centre of the press, and fits accurately into this cylinder, to the lower end of which is fastened the plattin; there is a flat side made to the cylinder, which is prevented from turning round by a bar of iron screwed across the two cheeks, and bearing against the flat side of the cylinder; the lever apparatus has likewise been improved by Mr. Keir. In the lower end of the spindle he has a screw cut and fitted into a nut; the spindle is made to rise and fall through a space equal to the descent of the great screw in the same time, and the connecting rod O is thus made to pull in a horizontal plane, while in the old construction one end remains level when the other descends, the consequence of which is an unequal wearing of the joints.

Ruthven's
press.
Pl. lxxx.
Fig. 4, 5.

(1080.) *Ruthven's printing press.*—This is represented in 4, 5, where A A is the tablet which sustains the form of types which remains fixed in the same position: this bed is supported by a framing of cast iron as shown in the figures; P P shows the plattin, and is joined to a strong cast-iron bar M M by screws *s, s*. At the ends of this bar there are strong iron bolts *b, b*, secured by screw nuts at the top; the bolts terminate below in heads or projecting pieces, which fit exactly the hooks or clutches at E, E; at each of the remotest ends of the bar M M is fixed an oval steel spring, and on the lower ends of each spring are two grooved wheels or rollers, which run on a railway, so that the whole plattin may be pushed off the form of types after it has given the pressure and again brought above M to press the succeeding sheet. These springs have their elasticity and form so adjusted that the lower surface of the plattin is raised above the margin of the tympan when the springs are not in action. The plattin, therefore,

readily moves into its position immediately above the tympan, and, as soon as it is pressed down upon the types, the action of the spring raises it above the margin of the tympan, and permits it to be pushed aside by the handle *h* from the form of types. We have already mentioned that the lower ends of the bolts *b, b*, which are generally shaped like the frustum of a wedge, go into a hollow of the same form when the plattin is pulled above the types; the object being to lock the plattin to the compound lever E F G H K L, which, when moved by the handle *h*, presses the plattin upon the types. This part of the apparatus consists of two levers, D F, D F, moving upon fixed centres at D, D; the clutches, of wedged-shaped cavities, are joined to these levers near the fulcra D, D, so that when the extremities F, F of the levers D F, D F are pulled down, the clutches are also pulled down, and therefore bring down the plattin to which they are locked. The descent of the ends F, F is produced by a link G united to both, and this link is again joined to another lever whose fulcrum is at K, while the other end is connected with the handle *h*, by which the pressure is given. These levers are so arranged that the maximum force is given when the plattin just begins to touch the tympan. The plattin in Mr. Ruthven's large presses is the size of a full sheet, and, in consequence of the pressure not being propagated from its centre, the pressure over the whole sheet becomes more equable than in other presses.

(1081.) *Printing machines.*—Notwithstanding all the ingenuity which had been exercised in improving the printing press, its powers, as we have already observed, were inadequate to the demand created by the general spread of education and spirit of inquiry amongst the English people. After all the improvements, a single press could only work off at an ordinary rate about 250 impressions or 125 sheets per hour; and although, by excessive labour, a greater number were produced in our newspaper printing-offices, yet it was necessary to have duplicate presses and set up forms of type to carry on such work, and still the production of copies was quite inadequate, in point of time, for our increased rapidity of transfer from the metropolis to the distant parts of the Country. Hence the absolute necessity for some great change in the Art of printing; and the first attempt was, we believe, made in 1790 by the late ingenious Mr. William Nicholson, who procured a Patent for his invention, which embodied, in point of principle, much of what has since been effected.

Mechanical
Processes.

Printing
machines,
invention
of.

First Pa-
tent by Mr.
Nicholson.

It is uncertain whether or not Mr. Nicholson's views were known to Mr. König, a German, but to the latter is, at all events, due the honour of having first carried steam printing into effect.*

Mr. König, conceiving it possible to apply steam-power to produce accelerated speed with the common press, after various unavailing efforts to obtain assistance from the printers on the Continent, came to England, and arriving in London about 1804, he submitted his scheme to several printers there with no better success, until he was introduced to Mr. Bensley, senior, who, attracted by Mr. König's plans, entered into arrangements with him. After persevering for some

König's
Patent.

* Mr. König having claimed the invention of *cylindrical* printing, Mr. Cowper once asked him if he was aware of what Nicholson had done, and Mr. König said, "He had made a point of not reading any thing that other persons had done, in order that the machine might be entirely his own invention."

Manufac-
tures.

time in various attempts to accelerate the speed of the common press, and at the same time to render the attendance of the man who inks the types unnecessary, his exertions resulted, to use his own words, "in discovering that they were only employing a horse to do what had been before done by a man." He in consequence gave up all idea of his projected improvements of the common press, and turned his attention to cylinder printing.

After continued experiments for some years, a small machine was made, in which the leading features of Nicholson's invention were embraced, which he exhibited to Mr. Walter, proprietor of the *Times* newspaper; and, on showing what further improvements were contemplated, an agreement was entered into for the erection of two machines for printing that journal. Accordingly, on the 28th of November, 1814, the public were apprized that the number of the *Times* of that date was the first ever printed by machinery, steam propelled. Mr. König subsequently made a machine to print both sides of the sheet before leaving the machine. Both these machines were extremely ingenious, but the inking apparatus, containing forty wheels, was very complicated, and sometimes occupied two hours to get it into working order.

Applegath
and Cow-
per's Pa-
tent.

Notwithstanding the ingenuity displayed in the construction of this machine, it was soon superseded by that of Messrs. Applegath and Cowper, who, in the year 1818, took out a Patent for performing the operation of steam printing; the main principle of which, as characteristic of the invention, consisted of the application of two drums placed between the cylinders to ensure accuracy in the register, over and under which the sheet was conveyed in its progress from one cylinder to the other, and in the mode of distributing the ink upon the tables instead of rollers; two principles which have secured to machines of this construction a decided preference for fine works. Machines of this construction have been made by Messrs. Applegath and Cowper for the principal printing establishments in London, Paris, Edinburgh, and other Cities.

Present
variety of
printing
machines.

Printing machines are now made of various kinds, adapted to the peculiar descriptions of work for which they are required. These descriptions of work may be classed under two distinct heads, namely, the printing of newspapers one side at a time, and the printing of a better kind of sheets, or book-work, both sides at a time. There can be nothing more easy than to make a machine capable of first printing one side of a sheet of paper, and afterwards the second, by the removal of one form and the introduction of another; but this process will not produce *register*: the second side may or may not be on the back of the first, and the work is therefore of a very inferior appearance, though suitable enough for newspapers, in the working of which despatch is alone required. This kind of press is therefore the best adapted to gain that end; for the first side of the paper may be printed deliberately, and the second side be made up to the last moment of time, and then thrown off. To produce a machine to print both sides at a time, and with perfect register, no small degree of mathematical accuracy, and no small share of ingenuity in the mechanician, are required. The great and important object to be attained in this kind of machine is to cause the sheet, after it has received its first impression, to travel along the sides of the cylinders and drums at such a rate as to meet the types of the second side at the exact point which will cause the second side to fall with

Mechanical
Processes.

perfect accuracy upon the back of the first. To accomplish this exceedingly desirable end, the cylinders and drums must revolve at precisely the same speed as the carriage underneath; and therefore any inaccuracy in the turning of the axles, the cutting of the teeth of the wheels, or any other deficiency, however slight, will produce badly registered sheets, and create an enormous degree of vexation to the printer. It is of equal importance that the ink should be perfectly "distributed," and that the face of the type should be perfectly covered without being *smothered* with ink, and that the whole of the inking apparatus should be under complete control, and easily put into working order.

The first persons who succeeded in these great desiderata were the Patentees last mentioned; for although, as we have seen, Mr. König was the first person who brought the printing machine actually into operation, the invention was still far from being completed, much still remaining to be effected. It is therefore to Messrs. Applegath and Cowper we must consider ourselves indebted for the astonishing perfection to which these machines have now arrived, as will appear more fully from the following description of two of their machines, in the course of which some historical facts are referred to which have been hitherto much misrepresented.

Applegath and Cowper's Printing Machine.

(1082.) This machine, represented in fig. 1, plate lxxxi., is adapted to print both sides of the sheet of paper before it leaves the machine, and it prints from 800 to 1000 sheets per hour on both sides, the common press printing only 125 sheets on both sides in the hour.

Applegath
and Cow-
per's print-
ing ma-
chine.
Pl. lxxxi.
Fig. 1, 2.

The supply of blank paper is laid on a table A, whence the sheets are taken one by one by a boy standing on an elevated platform who lays them out on the feeder B, which has a number of linen girths passing across its surface and extending round a roller at each end of the feeder, so that, when the rollers are partially turned round, the motion of the girth carries the sheet forward and delivers it over the entering-drum E, where it is seized between two systems of endless tapes passing over a series of rollers to keep them extended. These endless tapes are so adapted in number and position as to fall between the pages of the printing, and also on the outsides of the printing, *i. e.* the edges of the sheet; they may therefore remain in contact with the sheet of paper on both sides during its whole passage through the machine, by which means the paper is conveyed from the printing cylinder F to the other printing cylinder G without destroying the "register," *i. e.* the coincidence of the pages on the opposite side of the sheet. F and G are the printing cylinders, which are made of iron and turned perfectly true, and are clothed with fine woollen cloth, technically called *blanket*, in those parts where the sheet falls to receive the impression; they are mounted on strong axes which turn in bearings affixed to the main frame of the machine. The bearings are adjustable by screws to every degree of pressure. H and I are the conveying drums; they are made of wood, and convey the sheet steadily from one printing cylinder to the other.

The manner in which the endless tapes (before mentioned) are arranged is as follows. We will suppose one system of tapes to commence at the upper part of the entering-drum E; thence they proceed in contact with the right-hand side and under portion of the printing

Manufac-
tures.

cylinder F; they then pass *over* the conveying drum H and *under* the conveying drum I, whence they proceed to encompass the left-hand side and under portion of the printing cylinder G, and, by passing in contact with the small rollers *a, b, c, d*, they arrive again at the roller E, whence they commenced, thereby forming one of the systems of endless tapes; the other system we will suppose to commence at the roller *h*. They are equal in their number to the tapes already described, and correspond with them also in their places on the cylinders, so that the sheets of paper may be held securely between them. These second tapes descend from the roller *h* to the entering-drum E, where they meet and coincide with the first system in such a manner that the tapes proceed together *under* the printing cylinder F, *over* H, *under* I, and round G, until they arrive at the roller *i*, when they separate, having remained thus far in actual contact, except at the places where the sheets of paper are held between them. From the roller *i* the tapes descend to a roller at *k*, and by passing in contact with rollers at *l, m, n*, they arrive at the roller *h*, from whence they commenced; thus the two systems of tapes act continually in concert without interfering with each other. See diagram, fig. 1. The cylinders and drums are all connected by toothed wheels, so as to insure a uniform and steady motion.

The two separate forms of type are placed at a certain distance from each other on a long carriage, and an inking table, *i. e.* an extended metal surface, is also placed on the carriage and close to each form. The carriage, with the two forms of type and the two inking tables, moves backwards and forwards from one end of the machine to the other on rollers attached to the main frame of the machine, and in its journey bringing the types in contact with the sheet of paper on the circumference of the printing cylinders. This reciprocating movement is produced by a pinion working into the alternate sides of a rack under the tables, motion being given to the pinion by the bevel wheels K. The mechanism for furnishing the proper quantity of ink for *distributing*, *i. e.* equally spreading it over the inking table and finally applying it to the types, performs its operations with great delicacy and certainty. This is a very important part of the machine, a single *grain* of ink being frequently sufficient for one side of a sheet.

Two similar and complete sets of inking apparatus, one at each end of the machine, are adapted to ink their respective forms of type; we will therefore describe one, a metal roller L, called the ductor roller, which has a slow rotary motion communicated to it by a catgut band passing round a small pulley upon the end of the axis of the printing cylinder G. A horizontal plate of metal, the edge of which is ground straight, is adjusted by screws so as to be almost in contact with the ductor roller; a back is put to the horizontal plate, so that the whole forms a sort of trough in which the mass of ink is placed, and as the metal roller revolves it becomes covered with a thin film of ink. An elastic composition roller, called the vibrating roller, is made to vibrate between the ductor roller and the inking table; when the vibrating roller rises, it touches the ductor roller and takes a small portion of ink, and when it descends, it deposits the ink on the inking table. Three or four rollers of small diameter, called distributing rollers, are placed across the machine at M. They are not placed *directly* across, but in a somewhat diagonal direction, being about two inches out of the perpendicular; the spindles

of the distributing rollers are made long, and they lie in notches and not in fixed bearings. As the table moves under them, they not only rotate but also have an end-motion, *i. e.* a motion in the direction of their length, in consequence of their diagonal position, and this compound motion obliterates all inequalities and produces a perfect *distribution* of the ink on the inking table; the inking table then passes under the three or four inking rollers N, to which it conveys the distributed ink, and they, in their turn, ink the type; thus each time the type passes to and fro, *i. e.* for every sheet printed, the form is touched no less than eight times by the inking rollers. The distributing rollers and the inking rollers all turn in notched bearings, leaving them at liberty to move up and down, in order that they may bear with their *weight* on the inking table and the form; they therefore require no adjustment by screws, but are ready for work by merely being dropped in their notched bearings.

The machine is put in motion by a strap from a steam-engine to a rigger at the back of the machine, or by a fly-wheel turned by hand; they require but little power to turn them. Messrs. Clowes of Stamford-street have twenty of Applegath and Cowper's machines worked by two five-horse engines.

The operation of printing is performed as follows. The sheets of blank paper are laid one by one on the feeder B on the linen girths; the rollers C and D are now caused to move a portion of a revolution (by means of a segmental wheel.) This motion advances the sheet of paper sufficiently to enable it to enter between the two systems of endless tapes at the point where they meet each other on the entering-drum E. As soon as the sheet is fairly between the tapes, the rollers C and D are, by the operation of a weight, drawn back to their original position ready to advance another sheet into the machine. As the sheet is carried along between the endless tapes, it applies itself to the blanket on the printing cylinder F, and as it revolves it meets the first form of types and receives the impression from them; the sheet now printed on one side is carried over H and under I to the blanket on the printing cylinder G, at which place it will be found in an inverted position, the printed side being in contact with the blanket and the blank side outward, which, upon meeting the second form of types at the proper instant, receives the second impression and completes the sheet. On arriving at the point *i*, where the two systems of tapes separate, the perfect sheet is thrown out into the hands of a boy. An engraving and description of this machine appeared in the *Literary Gazette*, October 26, 1832, where it is called "Bensley's machine." This is a mistake, as Applegath and Cowper are the inventors, patentees, and actual makers of the identical machine from which the engraving was made. It is, therefore, only in the sense of his having *purchased* that machine of the Patentees that it could be called "Bensley's machine." The mistake, however, has been perpetuated by the *Encyclopædia Britannica*, and by Hansard's *Typographia*, both of which have copied the engraving, with its erroneous title and description.

These are the machines which are now in general use, all the large publications of the present day being printed by them, the *Encyclopædia Metropolitana* among the number; indeed, without them, such Works as the *Penny Magazine*, the *Saturday Magazine*, *Chambers's Journal*, and the *Magazin Pittoresque* and *Magazin Universel*, of Paris, could not exist. Of these

Mechanical
Processes.

Manufactures. useful Works upwards of 350,000 copies are printed every week by Applegath and Cowper's machines.

Inking table. (1083.) *Inking table.*—The success which attended the system of inking in the printing machine induced Messrs. Applegath and Cowper to apply the same principle to the common press. A representation of this contrivance is shown in fig. 1, plate lxxxii. It consists of an ink trough composed of a straight edge and ductor roller as in the machine above described, and an inking table and hand-inking roller; the ductor roller being turned round by hand becomes covered with a film of ink, the hand roller, mounted on a spindle and furnished with handles, is dabbed against the ductor roller, and then rolled backward and forward on the table, and then rolled over the type: this invention has formed an era in the Art of printing, for it has raised the quality of printing all over the world. Work, such as the first editions of the *Encyclopædia Britannica* and Rees's *Cyclopædia*, which in those days was considered good, would now not be tolerated for a newspaper or a tract.

Mr. Donkin is the inventor of the elastic composition roller, but he only introduced it in an unsuccessful machine, and never applied it to the common press.

In Hansard's *Typographia*, p. 630, this invention of the hand-inking apparatus, Mr. H. suggests, may be the simultaneous invention of Mr. Forster and Mr. Harrild, declaring it very difficult for him to assign the palm of priority to either. This difficulty arose from the simple fact that it was the invention of neither, but was the invention and Patent of Mr. Cowper, and both Mr. Forster and Mr. Harrild were merely *agents* appointed by Messrs. Applegath and Cowper for the sale of the apparatus.

The small diagrams in plate lxxxii. will give a general idea of the varieties of inking apparatus and arrangement of machines, and is in fact an epitome of the history of printing machines. Fig. 2 is Nicholson's machine for arched type; fig. 3 is Nicholson's for common type; fig. 4 is König's machine for one side of the sheet; fig. 5 is König's for both sides; fig. 6 is Donkin and Bacon's for one side; fig. 7 is Cowper's for curved stereotype and one side of the sheet; fig. 8 is Cowper's for curved stereotype and both sides of the sheet; fig. 9 is Applegath and Cowper's for one side and for common type; and fig. 10 is Applegath and Cowper's for both sides of the sheet, *i. e.* the machine above described.

(1084.) *Applegath and Cowper's Newspaper Machine at the Times' Office.*

As one side of a daily paper contains advertisements and matter of little importance, one side is generally printed sometime before the second side, which contains the debates in Parliament and the latest news; the great object, therefore, in a newspaper like the *Times* is to obtain as many impressions as possible from *one* form.

This was accomplished by making the form pass under *four* printing cylinders, the cylinders being made to rise and fall, in order to use cylinders of small diameter and thus bring them near to each other, and consequently shorten the journey of the form to and fro as much as possible. As two men cannot stand at the same feeders at the same time, two additional feeders were placed as it were on an *upper floor*, in order to supply the cylinders with paper.

Fig. 2, plate lxxxii., is a diagram of the machine invented by Applegath and Cowper for the *Times* newspaper.

In this machine there are four places to lay on the sheets and four to take off, consequently eight lads are employed to attend the machine. P, P, P, P are the four heaps of paper; F, F, F, F the four feeding boards; E, E, E, E the entering-drums on which the sheets enter the tapes *t, t, t, t*, whence they are conveyed to 1, 2, 3, 4, the printing cylinders; T the form of type; I I two inking tables, one being placed at each end of the form. The inking apparatus is similar to that in the machine already described, with the addition of two central inking rollers R, R, which also receive their ink from the inking tables. The printing cylinders 1, 2, 3, 4 are made to rise and fall about half an inch, the first and third at the same time, and the second and fourth at the same time. As the form of type passes from A to B it prints sheets at 1 and 3, and as it returns from B to A it prints sheets at 4 and 2; the cylinder alternately falling to give the impression, and rising to allow the form to pass.

Each of the lines marked *t* consists of two endless tapes running in contact in the parts shown, but separating at the entering-drums E, and at the taking off part o, o, o, o, the *return* of the tapes to the entering-drum being omitted to avoid confusion.

Operation of the machine.—The sheets being laid on their respective feeding boards with the fore edge just lying on the entering-drum, at proper intervals, a small roller, called the drop-down-roller, drops down on the edge of the sheet; the drum and the roller being in motion the sheet is instantly carried forward, between the tapes *t*, down to the printing cylinder, and thence upwards to o, o, o, o, where the tapes separate and the sheet falls into the hands of the boy.

The machine is under such complete management, that it is generally in full work within four minutes after the form is brought into the machine room.

The speed of König's machine by which the *Times* was formerly printed was 1800 per hour. The speed of Applegath and Cowper's machine is 4200 per hour, and it has been in daily use for more than six years.

Copper-plate Printing.

(1085.) This relates to working off engravings from copper, or other metal plates, and, in point of antiquity, is nearly of the same age with the Art of printing with movable types, having been first practised during the XVth Century. The subject of engraving, considered as one of the Fine Arts, has been already examined at considerable length under that division of this Work. Our only business here, therefore, is with the mechanical parts of the process, of which printing is the principal; but to prevent unnecessary reference, we shall say so much on the more common description of engraving as may be required for the purpose of those who look only to the mechanism of the process; those who wish for more minute information must consult the article referred to.

(1086.) *Engraving with strokes* is undoubtedly the most ancient, and, although a slower process than the other species of engravings, is still practised where extreme delicacy is required. Here the copper-plate intended to be engraved should be perfectly polished, very level, and free from every imperfection; to this must now be transferred an exact copy of the outlines of the drawing. To do this the plate is heated in an oven or other-

Manufac-
tures.

wise very uniformly till it is sufficiently hot to melt white wax, a piece of which is then rubbed over it and allowed to spread so as to form a thin coat over the whole surface, after which it is left in a horizontal position till the wax and plate are cold. A tracing being taken of the original design with a black-lead pencil on a piece of thin tracing paper, this is spread over the face of the prepared plate with the lead lines downwards, and, being secured from slipping, a strong pressure is made use of by a press or otherwise, by which operation the lead lines are nearly obliterated on the paper, being transferred to the white wax on the plate. These pencil marks on the wax are now traced with a fine steel point, so as just to touch the copper; the wax being then melted off, a perfect outline will be found on the copper, and on this the engraver proceeds to execute and finish his work.

The implements used for the purpose are *gravers* of various forms, a *scraper* for removing the burs which naturally follow the graver, a *burnish stone*, *oil stone*, *oil rubber*, *rullers*, *compasses*, *parallel*, *charcoal*, &c. With respect to the process itself it would be useless to speak; it depends on a manual dexterity and genius which it is impossible to teach by description.

Etching.

(1087.) *Etching*.—Here the plate, instead of being covered with white wax, is coated with a composition of a resinous description which dries harder than the wax, and at the same time resists the action of the acid afterwards to be employed. A copy of the drawing is transmitted to the thin coating on the plate in a manner similar to that above described; this is now traced over with a fine steel point, whereby the composition is removed from those parts and the copper exposed; a wall or border is then formed round the edge of the plate of a composition of wax softened by Burgundy pitch or tallow, and the plate being laid flat a quantity of dilute nitric acid is poured on to the depth of about half an inch; this immediately acts upon the parts of the copper laid bare by the tracing, and bubbles, proceeding from the decomposition of the metal, &c., will rise, which must be carefully removed with a feather as fast as they appear, and also all such as are observed to adhere in the strokes. When the subject to be engraved is a mere outline or very plain figure, the acid, being left to act for a greater or less time according to circumstances, is poured off, and the composition being also removed, it will be found that all the lines previously traced on the composition are now transferred to the copper-plate, but commonly requiring to be finished off with the graver.

In more delicate designs, however, this simple process is not sufficient; parts of the drawing are lighter than others, and on the plate the lines must be less deep; in these cases the process is as follows. When the faintest parts of the design are supposed to be sufficiently bitten the nitric acid is poured off and the plate washed with water, leaving of course the composition on. These light parts are then covered with what is called a stopping mixture, to prevent the further action of the acid on those parts, the acid is then again poured on, and the same operation repeated as often as is necessary to produce all the different degrees of strength in the different parts. The plate is then heated and some olive oil poured on to facilitate the removal of the composition, which being effected, the engraver proceeds to complete the work thus commenced by the acid with the graver, scraper, burnisher, &c., as already described in the former mode of engraving.

It may be observed that etching, in its original sense,

was supposed to imply the simple process of etching without the aid of the graver, but it is very seldom that such is the case; so also in original engraving, the graver is supposed to be employed independently of acid; but in the present state of the Art professed etchings are seldom made without some finish from the graver, and few engravings without the previous assistance of acids.

(1088.) *Mezzotinto engraving*.—Here the plate is prepared by polishing, &c., as for other kinds of engraving, and is afterwards divided equally by lines parallel to each other which are traced out with very soft chalk. The distance of these lines should be about one-third of the length of the face of the grounding tool which is to be used, and they should also be marked by letters or otherwise to distinguish them from each other. The grounding tool is then placed between the two first lines and passed forward in the same direction with them; it must be held as steadily as possible and pressed upon with a moderate force, rocking it from end to end till it has completely hacked all the parts of the plate between those two lines; the same operation must be repeated with respect to all the other lines till the tool has passed over the whole surface of the plate and rendered it uniformly rough throughout. Other lines must then be drawn across the plate at right angles to these, and the operation above described repeated. Similar lines are now drawn diagonally, and these again are crossed at right angles to themselves with other lines, the grounding tool being still used the same in all: this forms what is called the first order of lines. These are now followed by the second order, which have the same breadth as the first, but they are laid on so as to divide those already made into spaces one-third less than their original width. Then follows the third order of lines, at the conclusion of which the plate is said to have had one turn; but to produce a very uniform dark ground these several operations require to be repeated several, perhaps twenty, times.

This process being at length completed, the sketch of the design or outline must be chalked on it by rubbing the back of the paper or drawing with chalk, and tracing the outline with a pointer, as in etching. It is also proper to overtrace it afterwards with black lead or Indian ink, in order to produce a more distinct and permanent sketch. The operation of the engraver now commences by his scraping away the grain of the ground in various degrees, so that none of it is left in its original state except in the touches of the strongest shades, the general method of proceeding being similar to that of drawing with white upon black paper. The masses of the strongest lights are first begun and scraped pretty smooth, and some parts, where there is no shade, are burnished, and those parts which go off into the light in the upper part but are brown below. The next lower gradations of shade are then scraped down, after which the reflected lights are entered upon. The plate is next blackened with a printer's ball made of felt, in order to discover the effect; the work is then proceeded with again, again examined, and so on till the desired effect is produced.

(1089.) *Aquatinta*.—This is a method of producing prints very much resembling drawings in ink. The principle of the process consists in corroding the copper with aquafortis in such a manner that an impression from it has the appearance of a tint laid on the paper. This is effected by covering the copper with a powder of some substance that will take a granulated form, so as to

Mechanical
Processes.

Mezzotinto
engraving.

Aquatinta
engraving

Manufac-
tures.

prevent the acid from acting where the particles adhere, and by this means corroding the copper partially, and in the interstices only. When these particles are extremely minute and near to each other the impression from the plate appears to the naked eye exactly like a wash of Indian ink, but when they are larger the granulation is more distinct; and, as this may be varied at pleasure, it is capable of being adapted with success to a variety of subjects.

The substances which have been mostly used for this purpose, either separately or mixed, are asphaltum, Burgundy pitch, resin, gum copal, and gum mastic; and in a greater or less degree all resins and gum resins will answer the purpose. Common rosin is most generally used and has been found to answer very well, though gum copal makes a grain that resists the aquafortis better. The substance intended to be used for the grain must be distributed over the plate as equally as possible, and different methods of performing this essential part of the operation have been used by different engravers, and at different times. The most usual way is to tie up some of the powder in a piece of muslin and to strike it against a piece of stick held at a considerable height above the plate; by this means the powder that issues falls gently and settles equally over the plate. The plate being thus covered over with the dust or powder, the operator is next to proceed to fix it upon the plate by heating the latter gently so as to melt the particles. This may be effected by holding lighted pieces of paper under it and moving them about till all the particles are melted, which will be indicated by its change of colour. The plate is now left to cool, when it may be examined with a magnifier, and if the grains or particles appear to be uniformly distributed, it is ready for the next part of the process. The design or drawing to be engraved must first be examined, and such parts of it as are perfectly white are to be re-marked, and the corresponding parts of the plate must be covered or stopped out with turpentine varnish diluted with turpentine to a proper consistence to work freely with the pencil, and mixed with lamp-black to give it colour, for, if transparent, the touches of the pencil would not be so distinctly seen; the margin of the plate must also be covered with varnish, and when the stopping out is sufficiently dry a border of wax must be raised round the plate in the same manner as described under etching, and the acid, properly diluted with water, poured on. This part of the process, called the biting in, is the most uncertain, and requires skill and experience.

When the acid has remained on a sufficient time to produce the lightest shade in the drawing, it is poured off, and the plate washed with water and dried; the lightest parts being now stopped out as described in etching, the acid is again poured on, and the process repeated as often as necessary. Many plates are etched entirely by this method of stopping out and biting in alternately, yet it may be easily conceived that, in general, it will be difficult to stop round and leave out all the finishing touches, as also the leaves of trees and many other objects.

To avoid these difficulties, another process is sometimes had recourse to by which these touches are laid on the plate with the same ease and expedition as they are on a drawing of Indian ink. Fine washed whiting is mixed with a little treacle or sugar and diluted with water in the pencil so as to work freely, and this is laid on the plate covered with the aquatint ground in the

VOL. VIII.

same manner and on the same parts as the ink on the drawing. When this is dry, the whole plate is varnished over with a weak and thin varnish of turpentine, asphaltum, or mastic, and then left to dry; the aquafortis is then poured on. The varnish now breaks up in the parts where the treacle mixture was laid, and thereby exposes all those places to the action of the acid while the rest of the plate remains secure. The effect of this is that all the touches or places where the treacle was used will be bit in deeper than the rest, and will have all the precision and firmness of touches of Indian ink.

After the plate is completely bitten in, the bordering of wax is taken off by heating the plate, as already described under etching; it is then cleared from the ground and varnished by oil of turpentine, and wiped clean with a rag and a little fine whiting, when it is ready for the printer.

Other means are sometimes employed, but perhaps sufficient has been said on a subject which is scarcely a part of our general design.

(1090.) *Engraving in chalk.*—This is a species of Chalk engraving. engraving. intended to imitate drawing in chalk, and is capable of great effect. It is a kind of etching by dots, the principal difference between it and the usual etching being, that the several shades, &c., in the work are produced by dots instead of strokes. The plate is prepared and the ground laid exactly as described, (Art. 1089.) and the drawing traced also in like manner. The outline of the drawing must now be formed by etching in points which will form dots whose size and distance must depend upon the strokes in the original drawing. In forming the lights and shades, it is necessary to distinguish those hatches which serve to express the perspective of the object from those which form the ground. The latter are marked strongly, the middle tints lightly, and the weaker are last reserved to be performed dry with the graver. The acid being applied as described under etching, when the lighter shades are sufficiently bitten in the acid must be poured off, and those parts stopped with turpentine varnish. The acid is then again poured on and left to act till the next deeper shades are produced, and so on, as in etching. The ground is now removed, and the finer dots introduced with the graver as above stated.

The principal object of this kind of engraving is to imitate drawings in chalk. The stroke of the chalk in the drawing is a succession of small dots where the chalk passes over the asperities or eminences on the surface of the paper, and it is these irregular dots which are produced with this kind of etching. In many cases the imitation is exceedingly close, so that an artist is sometimes almost unable to distinguish between the copy and the original. Drawing in different-coloured chalk may be imitated by this kind of engraving if a plate be made for every colour, which of course is laid on one after the other in the printing. The French have very well imitated drawings on blue paper by using two plates, from one of which the black chalk effect is produced, and from the other the effect of the white chalk. Chalk plates, likewise printed on black or blue paper, may afterwards be touched with white chalk, thereby producing a very good effect.

(1091.) *Engraving on steel.*—Some of the earliest Engraving on steel. engravers, particularly Albert Durer, used steel plates for engraving, but they were afterwards wholly rejected for those of copper. Within a few years, however, the arts of decarbonizing and recarbonizing steel have been carried to a great perfection, and engraving on steel is now very commonly executed for works which call for a great

5 H

Manufac-
tares.

number of impressions, the steel plate allowing many more copies to be taken than the copper one before it is deteriorated. The method of engraving is the same as copper-plate engraving, except in certain modifications in the use of the acids, and therefore, so far as the process is concerned, no particular description is necessary; but it will be proper to explain the means employed for decarbonizing the steel plate so as to reduce it to a proper state for being acted upon by the graving tool. Mr. C. Warren, an eminent English artist, has the merit of having re-established engraving on steel; he communicated his process to the Society of Arts in 1823, who awarded him their gold medal for his invention, but he unfortunately died before it was ready for delivery. An account of his process for decarbonizing the plate is given in the Society's *Transactions*, vol. xli. This has been since improved; and, as we shall describe the method employed by Messrs. Perkin, Heath, and Co., in a subsequent article, it will be sufficient to refer the reader, who is desirous of studying Mr. Warren's method, to the Work quoted above.

Method of
preventing
forgery of
bank-notes.

(1092.) *Engraving for preventing forgery.*—Another beautiful application of engraving on steel was introduced, about the same time as Mr. Warren's communication, by Mr. Perkin, an American engineer, who, with Messrs. Heath and Fairman, obtained a Patent for the invention; this was intended principally to prevent the forgery of bank-notes, which at that time, or rather previously to that time, had been carried on to a very fearful extent. According to this plan a steel plate, decarbonized as described below, is engraved or etched in the usual way; it is then recarbonized and rendered very hard. A cylinder of very soft or decarbonized steel is now made to roll under a great pressure backward and forward on the hardened engraved plate till the entire impression from the engraving is seen on the cylinder in alto-relievo. The cylinder is then hardened and made to roll again backward and forward on a copper or soft steel plate, whereby a perfect fac-simile of the original is produced of equal sharpness.

This ingenious process was to be applied for the prevention of forgery in the following manner. It was proposed in this way to produce a beautifully-executed design on a small scale by employing a first-rate artist, and to repeat its impression on the face of the note as often as might be thought desirable, every one of which would be so exactly alike that no magnifying power would be able to distinguish any difference; an accuracy of copy which it was supposed it would be impossible to imitate if engraved successively on the plate by the most able artists. To increase the difficulty of imitation, it was also proposed to employ several artists of the first rank to produce each a specimen, and to introduce them all on the same plate, which would of course increase the difficulty and expense of the plate; at the same time it was stated that, notwithstanding this great first cost, the entire expense to the Bank of England, after a very short time, in consequence of their extensive issue, would be lessened, the steel plates thus hardened lasting a much longer time serviceable than the copper plate would do. The change, however, which took place in the currency about the time this proposition was made caused it to be neglected, and we believe that at present it is but little practised. The method employed for decarbonizing and recarbonizing the plate, however, may be applicable to many other useful purposes, and we shall therefore give it in the words of the Patentees. "In order to decar-

bonate the surfaces of cast-steel plates, cylinders, or dies, by which they are rendered much softer and fitter for receiving either transferred or engraved designs, we use pure iron filings divested of all foreign or extraneous matters. The stratum of decarbonated steel should not be too thick for transferring fine and delicate engravings, for instance, not more than three times the depth of the engraving; but for other purposes the surface of the steel may be decarbonated to any required thickness. To decarbonate it to a proper thickness for a fine engraving, it is to be exposed for four hours in a white heat, enclosed in a cast-iron box with a well-closed lid. The sides of the cast-iron box are made at least three-quarters of an inch in thickness, and at least a thickness of half an inch of pure iron filings should cover or surround the cast-steel surface to be decarbonated. The box is allowed to cool very slowly, which may be effected by shutting off all access of air to the furnace, and covering it with a layer of six or seven inches in thickness of fine cinders. Each side of the steel plate, cylinder, or die, must be equally decarbonated, to prevent it from springing or warping in hardening. It is also found that the safest way to heat the plates, cylinders, or dies, is by placing them in a vertical position. The best steel is preferred to any other sort of steel for the purpose of making plates, cylinders, circular or other dies, and more especially when such plates, cylinders, or dies, are intended to be decarbonated. For the reason given above, the steel is decarbonated solely for the purpose of rendering it sufficiently soft for receiving any impression intended to be made thereon; it is therefore necessary that, after any piece of steel has been so decarbonated, whether it be in the shape of a plate, or a cylinder, or a die, it should, previously to being printed from, be again carbonated or reconverted into steel capable of being hardened. In order, therefore, to effect this decarbonization or re-conversion into steel, the following process is employed: a suitable quantity of leather is to be converted into charcoal by the well-known method of exposing it to a red heat in an iron retort for a sufficient length of time, or until most of the evaporable matter is driven off the leather. Having thus prepared the charcoal, it is reduced to a very fine powder; then take a box made of cast iron, of sufficient dimensions to receive the plate, cylinder, or die, which is to be reconverted into steel, so as that the intermediate space between the sides of the said box and the plate, cylinder, or die, may be about an inch. This box is to be filled with the powdered charcoal, and, having covered it with a well-fitted lid, let it be placed in a furnace similar to those used for melting brass, when the heat must be gradually increased until the box is somewhat above a red heat; it must be allowed to remain in that state till all the evaporable matter is driven off from the charcoal; then remove the lid from the box, and immerse the plate, cylinder, or die, into the powdered charcoal, taking care to place it as nearly in the middle as possible, so that it may be surrounded on all sides by a stratum of the powder of nearly an uniform thickness. The lid being replaced, the box, with the plate, cylinder, or die, must remain in the degree of heat before described for from three to four hours, according to the thickness of the plate, cylinder, or die so exposed; three hours are sufficient for a plate of half an inch in thickness, and five hours when the steel is one inch and a half in thickness. After the plate, cylinder, or die, has been thus exposed to the fire

Mechanical
Processes.

Method of
softening
and harden-
ing the steel
plates, &c.

Manufac-
tures.

for a sufficient length of time, take it from the box and immediately plunge it into cold water. Here it is important to observe that it is found by experience that the plates or other pieces of steel, when plunged into cold water, are least liable to be warped or bent when they are held in a vertical position, or made to enter the water in the direction of their length. If a piece of steel, heated to a proper degree for hardening, be plunged into water, and suffered to remain there until it becomes cold, it is found by experience to be very liable to crack or break, and in many cases it would be found too hard for the operations it was intended to perform. If the steel cracks or breaks it is spoiled; in order, therefore, to fit it for use, should it happen not to be broken in the hardening, it is the common practice to heat the steel again, in order to reduce or lower its temper, as it is technically called. The degree of heat to which it is now exposed determines the future degree of hardness, or the temper, and this is indicated by a change of colour upon the surface of the steel. During this heating a succession of shades is produced, from a very pale straw-colour to a very deep blue. It is found, however, by long experience, that on plunging the steel into cold water, and allowing it to remain there no longer than is sufficient for lowering the temperature of the steel to the same degree as that to which a hard piece of steel must have been raised to temper it in the common way, it not only produces the same degree of hardness in the steel, but, what is of much more importance, almost entirely does away the risk or liability of its cracking or breaking.

"It is impossible to communicate by words, or to describe the criterion by which we can judge of or determine when the steel has arrived at the proper degree of temperature after being plunged into cold water; it can only be learned by actual observation, as the workman must be guided entirely by the kind of hissing or singing noise which the heated steel produces in the water while cooling. From the moment of its being first plunged into the water the varying sound will be observed; and it is at a certain tone, before the noise ceases, that the effect to be produced is known. The only directions which can be given whereby the experimentalist can be benefited are as follows, *viz.*, to take a piece of steel which has already been hardened by remaining in the water till cold, and by the common method of again heating it to let it be brought to the pale yellow or straw-colour, which indicates the desired temper of the steel plate to be hardened. By the above process, as soon as he discovers this colour to be produced, to dip the steel into water and attend carefully to the hissing, or as some call it a singing, which it occasions; he will then be better able, and with fewer experiments, to judge of the precise time at which the steel should be taken out. It is not meant to be understood that the temper indicated by a straw-colour is that to which the steel plate, cylinder, or die, should be ultimately reduced, because it would then be found too hard, but merely that the temperature which would produce that colour is that by which the peculiar sound would be occasioned when the steel should be withdrawn from the water for the first time. Immediately on withdrawing it from the water, the steel plate, cylinder, or die, must be laid upon or held over a fire, and heated uniformly until its temperature is raised to that degree at which tallow would be decomposed; or, in other words, until a smoke is perceived to arise from the surface of the steel plate, cylinder,

or die, after having been rubbed with tallow; now the steel plate, cylinder, or die, must then be again plunged into water, and kept there until the sound becomes somewhat weaker than before. It is then to be taken out and heated a second time to the same degree by the same rule of smoking tallow as before, and the third time plunged into water till the sound becomes again weaker than the last; exposed the third time to the fire as before; and for the last time return it into the water and cool it; after it is cooled, clean the surface of the steel plate, cylinder, or die, by heating it over the fire; the temper must be finally reduced by bringing on a brown or such other lighter or darker shade of colour as may best suit the quality of the steel for the purpose to which it is to be applied."

Mechanical
Processes.

(1093.) *Copper-plate printing.*—The plates, whatever be the nature of the engraving, being finished by the artist, are next to be put into the hands of the copper-plate printer, the operation being performed by what is called a rolling-press.

Copper-plate print-
ing.

This machine, which is of very simple structure, is represented in plate lxxxii. fig. 11. It consists of two parts, the body and the carriage; the former is simply two cheeks of wood, or, as represented in the figure, of iron, A, A, placed vertically on a stand or foot B B, which sustains the whole machine; from this foot proceed also four other vertical pieces, a, a, joined by other cross or horizontal pieces, which serve to support a strong even plank of wood, or table, C D E, about four and a half feet long; two and a half feet broad, and about one and a half inch thick; within the cheeks are two rollers, F, G, the upper one iron the lower wood. These run in the cheeks on gudgeons formed of themselves by turning down their ends, on two pieces of wood in the form of half-moons, lined with polished iron to facilitate their motion. Lastly, to one of the gudgeons of the upper roller is fixed a cross, consisting of two or more levers, H, I, traversing each other at right angles, and by means of which motion is given to the upper roller. The space in the half-moons, left vacant by the gudgeons, is filled in old presses with paper, pasteboard, &c., that they may be raised or lowered at discretion, so as only to leave a space between them necessary for the carriage charged with the plate, paper, and blankets; but in modern presses this is more effectually done by a screw.

Common
press.
Pl. lxxxii.
Fig. 11.

The process of printing is as follows. A small quantity of ink is taken on a rubber made of linen rags strongly bound about each other, and then smeared over the whole face of the plate as it lies on a grate over a charcoal fire. The plate being sufficiently inked, it is wiped over with a piece of canvass, then with the palm of the left hand, then with that of the right, and to dry the hand, and forward the wiping, it is rubbed from time to time in whitening. It is in the wiping that the art of the printer consists; for this must be so effected that, while every particle of ink or dirt is removed from the surface of the plate, the ink already in the engraved parts must not be touched. The plate thus prepared is laid on the plank of the press, and over the plate is laid the paper which is to receive the impression, being first well moistened, and over the paper are laid two or three folds of blanket or flannel. Every thing being thus disposed, the arms of the cross are pulled, and by that means the plate, with its furniture, is passed through between the rollers, which, pressing strong, but equally, forces the moistened paper into the strokes of the engraving, by which it absorbs the ink and receives the impression.

Manufac-
tures.

Some works require to be passed twice through the press, others only once, according as the engraving is more or less deep, or the greater or less degree of blackness the print is desired to exhibit.

The ink usually employed for copper-plate printing is a composition of peach and apricot stones, the bones of sheep or ivory, well burned, (called Frankfort black,) mixed with well-boiled nut-oil, the whole ground together on a marble slab in the same manner as painters grind their paint.

There are usually three kinds of ink, thin, thick, and strong, only differing in their degree of cohesion; the strong is that used in the finer works. The stronger the ink the stronger must be the pressure, and this induces the printer sometimes to use too thin an ink, by which injury is frequently done to the impression.

Perkin's
copper-
plate press—
Pl. lxxxii.
Fig. 12, 13.

(1094.) *Perkin's improved copper-plate press.*—The press described below is the invention of Mr. Perkin, and appears to possess great advantages. The principal improvement consists in a new method of heating the plate or block; in the use of a tympan for the purpose of saving the expense of making the plates or blocks any larger than is necessary to receive the engraving, as well as to save the ink, and also time and labour in changing the plates or blocks. The manner in which these objects are effected will appear from fig. 12, 13. A A, &c., is the cast-iron frame of the press; B the upper cast-iron roller, on the axis of which is fixed the wheel C, with handles around it for the workman to pull by; D the lower cast-iron roller; E F the bed of the press, made partly of cast-iron and partly of wood; the part E is of cast iron, the better to resist the pressure of the rollers, and to convey the heat employed to the warm plate or block; the plate or block G is fixed upon the bed by means of screws passing through countersunk holes made in the bed from the under side of it, and into screw-holes made partly through the plate or block itself. The tympan H is a wooden frame covered with copper, and turning in hinges I, I, having an aperture in it large enough to enclose the plate or block, the sides of which aperture are made feathered edges, so as to overlay the bevelled edges of the plate or block, and prevent them from soiling the paper. The cast-iron part of the bed of the press, with the plate or block upon it, is heated by means of a block of cast iron, which is supported upon another plate with turned-up edges, and which block is removed and replaced by another from time to time as it cools. In use, the frame of the plate is inclined, the front end resting upon the floor, and the other being raised by two screws passing through screwed holes in the sill of the press frame, one of which screws is shown at L. The intention of this inclination is to cause the bed to return, after the impression is made, of its own accord; and, in order to admit of this, a portion of the roller B is removed, and three pair of additional rollers, M, are added for the bed to roll upon with more facility, each pair of rollers being fixed upon a separate axis, with the necks working in brasses.

The blankets N, N, are secured to the cast-iron bed at one end by the blanket-holder O, and the stretcher P is affixed to the end of them, from which cords, Q, pass over the pulleys R, R, and have weights, one of which is shown at S, hung to them. By this means the blankets are kept stretched and relieved from the roller, and prevented from matting or becoming dirty in use. The roller B is kept up when the bed is released by the two following contrivances: T is two wooden blocks

lying at the bottom of the chases in the press frame; Mechanical at each end of these blocks is fitted a screw nut, into Processes which are screwed two screws, having flat cylindrical heads, with notches or teeth cut around them, and which project beyond the sides of the press frame so as to be easily turned either way as required. Upon these heads the brasses are rested in which the necks of the axis of the roller B turn, and the roller can thereby be supported at the required height, as above mentioned.

Fig. 13 represents a cylindrical steel or copper-plate printing press; A A, &c., is the cast-iron frame of the press; B the main cylinder for holding the plates, which has a solid cast-iron cylindrical surface or rim, upon which the plates are firmly secured by means of screws fastened through holes made in the surface of the cylinder, from the inside of it, and entered into screw-holes made partly through the plates. The main cylinder is mounted on an axis with necks, each end of it turning in brasses fixed upon the tops of the two main upright standards of the press frame. C is the small cast-iron pressing cylinder, which can be adjusted so as to press with more or less force against the main cylinder B by the screws, one of which is shown at D; E E is the endless web or blanket passing over and carried forwards by the pressing cylinder C, and over the web cylinder F; the necks or axis of which cylinder turns in brasses fitted into sliding carriages with adjusting screws, one of which is shown at G, for stretching the web.

Upon the extended axis of the pressing cylinder C is fixed the drum or rigger H, which is driven by a band. I I receives its motion from the moving power. The plates J, J, &c., are inked by the roller K running into contact with them in succession as the main cylinder revolves, and which roller is inked from distributing rollers L and M, the latter of which receives the ink in the usual manner as printing machines, from a trough and ductor, and which therefore need not be here shown. The ink is more uniformly distributed over the plates by a hand-roller used by a workman; another ductor N is supported by baskets at each end of it to the main standard of the frame, in the manner used in calico-printing. The last-mentioned ductor scrapes or takes off the larger portion of the ink, the remainder being removed by several persons wiping it off in succession, and finally cleaning their surfaces in the usual way. The paper, properly moistened, may either be laid on the revolving web or blanket E E in sheets, and be taken away when printed, or may be in the form of one or more long sheets, which may be previously wound upon the reel P, the neck or the axis of which turns in semicircular gaps or notches, one of which is shown at Q, and passes below the ductor-roller R until it reaches the prop, after passing through which, and becoming printed, it finally passes over the roller S to be taken away. The courses of the endless web or blanket E E, &c., and of the long sheet of paper, are indicated by the arrows which are shown accompanying them in their progress. The standards which support the neck of the rollers K, L, M, N, are omitted in the drawing, but must of course be employed. *Newton's Journal of Arts.*

(1095.) *Machine for numbering bank-notes.*—The Bank of England notes are of course first printed from a copper plate, as described in the last article, but the numbering, dating, &c., are afterwards printed by a machine invented by the late ingenious Mr. Bramah. Machine for numbering bank-notes. Pl. lxxx. Fig. 6.

Manufac-
tures.

This machine was first described by Mr. Farey, in Rees's *Cyclopædia*, and again in Brewster's *Encyclopedia*, and has since been introduced into other Works of the same kind. The following abridged description is obtained from these sources. It was formerly the custom in the Bank of England to fill up the number and date of their notes in writing; but, in 1809, the machine we are about to describe was invented for this purpose by Mr. Bramah, and has since been constantly employed. The copper plates from which the words of the notes are printed are double, that is, they throw off two notes upon one long piece of paper; this paper, containing the two notes, is put into the machine, which prints upon them the number and date, the date remaining fixed for the day, but the number changing, one for every succeeding note printed. The number on the note is always repeated; it is first found over the words *I Promise*, and again over the word *Bearer*. Any number being thus printed, the unit figure changes to the next in order, then again to the next, and so on, till the change is required in the tens' place, so that without much attention on the part of the operator, and without the possibility of error, the numbering and dating are executed in the simplest manner imaginable, and with more than six times the expedition with which the same could be effected by hand. This is of great importance, and was more especially so during the issue of the one-pound notes. The machine by which this operation is effected is represented in section, as for a single note, in plate lxxx. fig. 6; it is only necessary to consider this of double length, and with two sets of circles, to form an idea of the machine for two notes, as above described. A A is a solid base of mahogany, to which the sides of the machine are securely and firmly screwed; these are cast iron, one only of which is of course seen in the figure. From one side to the other of the machine are three axes, H, C, D; to the latter is attached the handle F, which is raised and depressed by the operator, who is a clerk in the Bank; to this is attached the tympan E. When the handle is raised this plate may be opened, and the note to be numbered is introduced and placed in its proper situation by means of two guide pins; the plate is then shut and the note properly confined, there being two holes in the plate to allow the types containing the numbers to come in contact with the paper.

On the axis C are five brass circles, of which only one is seen in the figure; each of these has eleven teeth, in which are cut notches to carry the digits 0, 1, 2, 3, 4, &c., 9, and one blank; the other wheel H on the axis H has also eleven teeth, so that moving one tooth on the latter turns the other one tooth round. There are three wheels on the axis, although only one can be seen, two of which are in contact each with one of the brass wheels on the two ends of the axis D, and the other is a central one by which the motion is communicated. This motion is thus produced: when the handle F is raised nearly perpendicularly, where it is stopped by the fixed stud *d* coming in contact with the back of the handle, the tooth or claw *b* will have passed the upper tooth of the wheel H, which it does without resistance, in consequence of its freedom of motion on its joint; but in returning the handle to its horizontal position, the claw having no motion in the opposite direction, it catches the upper tooth and forces it round the interval of one tooth, and this again forces the wheel C also one tooth, and consequently changes the number one place, that is to say, from 0 to 1, or from 1 to 2, &c., the several types

being arranged in order round the wheel. Of the five circles on the axle C, for example, let us suppose the four right-hand ones to have their blank teeth all up, and that the tooth 1 is upon the right-hand wheel, and suppose the impression No. 1 made at the two ends or sides of the notes by the two outside wheels, and that the wheel H is in contact with these two outermost circles. Then the handle being thrown back, the note removed, and another introduced, the claw *b* will have passed the upper tooth of the wheel H as above described, and on returning it will catch and press forward this wheel one tooth, and this again the wheel on C, bringing now the digit 2 to the upper position; the impression being made, the same process, if repeated, will bring up No. 3, then No. 4, &c., to No. 9.

It is now necessary, having run through all the units, to bring up No. 1 on the wheel, which now becomes the tens' place, and which is done by making two strokes with the handle without printing; the axle H is now pushed on end by a proper nut so as to bring the wheel H in contact with the next brass circle; then, the blank being already up, the next stroke brings up the 0, making with the standing digit 1 the No. 10; the next stroke gives 11, then 12, 13, &c., to 19. The first wheel is now moved on by hand till 2 is the uppermost type; then, similar steps being followed, the Nos. 20, 21, 22, &c., are obtained, and lastly, 99; when the first wheel *a* becomes the place of hundreds, the second of tens, and the wheel H is again put on end to engage the third type wheel, and so on, to any extent short of 100,000, 99,999 being, of course, the highest number to be attained by five type-wheels only. There are some minutiae about the machine which it is difficult to describe without other drawings; but the general nature of its operation will, it is presumed, be tolerably well understood from the preceding description.

Lithographic Printing.

(1096.) Lithographic printing is a modern Art, the invention of which is due to Sennefelder, who made the discovery about the beginning of the present century; but it is only since the Peace in 1815 that lithography began to be considered of sufficient importance to be classed amongst the Fine Arts. The principles on which it rests are thus stated by Mr. Partington, in his *Engraver's Complete Guide*, viz.

1. That a line drawn with a pencil or fat ink on a stone adheres to it so strongly that mechanical means must be employed to remove it.
2. All those parts of the stone which are not covered with a layer of fat or grease receive, retain, and absorb water.
3. If over a stone so prepared a layer of greasy and coloured matter be passed, it will attach only to the lines made by the greasy ink, while it will be repelled by the wetted parts.

In fact, the lithographic process depends on the circumstance that the stone which has imbibed the water repels the ink, and that the same stone, when greased, repels water and holds ink. Thus, by applying and pressing a sheet of paper on the stone, the greasy, resinous, and coloured lines alone will be transferred to the paper, giving the counter-proof of what they represented on the stone.

By making a drawing on paper with prepared ink, and transferring it to the stone, impressions exactly like

Mechanical
Processes.

Principles
of the Art.

Manufac-
tures.

the original may be obtained, that is, not reversed, as is the case in engravings on copper.

All kinds of stone susceptible of being penetrated by a fat substance, and of imbibing water with facility, are proper for lithography, provided they are compact, take a good polish, and are of a light and uniform colour: all these advantages are found united in certain calcareous stones, which are furnished in abundance by the quarries of Solen-Hofen, near Pappenheim, in Bavaria. It is a carbonate of lime almost pure; and is found also in other places.

When the stone is prepared and polished, the artist may, without any other preparation, sketch his design as he pleases, and finish it with the crayon, the pen, or the pencil. The grain of the stone being uniform, and finer than the finest wove paper, he may execute his work in the most delicate manner: but sufficient stress cannot be laid upon the fundamental principle of the Art, for, well as the rules are known, they are still continually forgotten by artists, who think that, provided the drawing they have executed looks well to the eye, they have done all which is necessary, and that the printer must and can do the rest, forgetting that the face of the stone has, perhaps, been soiled during the execution of the drawing, either by chalk cuttings, by rubbing with paper kept under the hand, by perspiring fingers, and many other causes of failure, which occasion spots, that disappear the moment they have soiled the stone, to re-appear again, infallibly, in the printing. The artist is surprised at seeing all those spots come forth, and accuses the printer of that which proceeds entirely from his own want of care. It is clear that, were it not for the black contained in the chalk, an almost invisible drawing might be made on stone, which would come forth only in the course of printing: and this is the case with those spots which do not form part of the drawing, and have taken place from negligence; as they do not show, the artist considers them of small importance, and, entirely taken up with the drawing he is executing, he hopes and thinks that nothing will print but what he intends should print. Therefore, again let this plain truth be enforced, that a lithographic stone absorbs, with avidity, any grease applied to its surface, and, consequently, that any grease or dirt so applied will come forth in the printing, as well as that grease which is intended to constitute the drawing.

We have now to notice the various species of stone employed in the Art, and upon the choice of which the success of the work must materially depend.

Ink drawings are generally made on polished stones, as the grain necessary for a chalk drawing makes it unpleasant to draw with the hair pencil or the pen. Some persons, from ignorance, have made chalk drawings on a polished stone; these, however, invariably fail, as a stone with a proper grain is the first requisite for the success of a chalk drawing.

It is of the greatest importance that the grain of a stone for a chalk drawing be not too fine, and a little practice will soon show the artist which is the proper grain; if too coarse, the drawing, particularly the delicate tints, will look open and sandy, and the execution will be attended with great trouble, especially in making out the minute parts. On the other hand, if the grain be too fine, the chalk slips and draws greasy, the stone does not appear to bite, and there is difficulty in producing dark tints. Moreover, in the printing, the darker parts soon clog up, and from the stone approach-

ing to the polished state, the delicate tints do not hold, and soon break up. The ease with which chalk works on a well-grained stone will soon teach an artist to know when the grain is as it ought to be, and its facility is such as to make drawing with a pencil on paper afterwards meagre and poor; for there is a richness and fulness in drawing on a good stone, which, from the nature of the material, has more of the feel of painting with a brush than of drawing with chalk. This peculiar feel is the best criterion to judge of the right grain of a stone.

There is no difficulty in ascertaining the proper preparation of a polished stone, as it is sufficient that the face be well smoothed and free from scratches.

This last defect is also to be avoided in a grained stone, as scratches are often produced by a coarse grain of sand, which invariably prints like a white hair line.

Although it is impossible to draw with chalk on a polished stone, ink may be, if employed with judgment, applied with great advantage in chalk drawings.

The best way to see the grain of a stone is to incline it to the horizon, nearly at an angle of 45 degrees; by varying the position slightly, above and below this angle, a certain point will be found at which the light will catch all the little asperities, and show the grain very distinctly. An artist who will take the trouble to do this with every stone he works upon will learn to know, by the eye, whether the grain is too fine or too coarse.

Portraits admit of, and even require, a coarser grain than landscape, particularly if drawn in the stippled manner. Success is more certain, and the impressions will possess a degree of brightness which can never be attained with a finer grain. By employing a sharp-pointed pencil for the more delicate tints, and occasionally opening and picking with a needle those small specks which occur in working on a coarse stone, a clever artist can produce drawings which bear being placed next to the best specimens of copper-plate engraving.

It must, however, be borne in mind, that in every case, whether figures or landscape, a coarse-grained stone is by far a less evil than too fine a one, as a failure is often the consequence of too fine a grain; whereas a little more trouble in the execution of the drawing is the only risk which the artist runs in working on a coarse grain.

Dr. Forster, of Berlin, is, we believe, the first person who has published his own Work, written by his own hand. It is entitled *An Introduction to General Geography, and preparatory Lessons of Geometry*, by Dr. Frederic Forster.

The author apologizes for his hand-writing in the following terms: "This book appears as a fac-simile manuscript. Young readers will not find the few pages fatiguing to their eye, and elder readers are accustomed to the reading of letters written in less clear and legible characters than mine. We do not find that writing, provided the impression be good, fatigues the eye."

The great convenience of being able to insert the figures between the writing, in mechanical and mathematical works, shows itself here to advantage; and it is probable that other works, requiring figures, plans, calculations, &c., will be executed on stone in a similar manner.

(1097.) *Description of the press.*—A A A, plate lxxxii. Lithographic press, fig. 14, are the supports of a strong table, on which is

placed the cast-iron press, consisting of two heavy iron sides, B C B, which are securely attached by screws to the centre part D D, which is also a thick cast-iron plate with a hole in its centre, as shown in the figure; from the sides are continued two iron slides *b, b*, only one of which is seen, and on these slides and a roller beneath, attached to the handle H H, the bed of the press G moves; E E is a frisket, beneath which the stone is laid, resting on the bed; there are screws and nuts at *tt* by means of which the sheet of leather, by which this is formed, may be brought to a proper degree of tightness; the handle M (shown larger in fig. 15) is hung on a joint at J, having another joint at K, and the descending axis S has a piece of hard wood fixed to it below, and which is adjustable by means of a nut running on S, so as to produce the proper degree of pressure.

It will be seen that when the handle M is pulled down, as represented in the press, the joint K (fig. 15) comes vertically below J, and the board I is depressed so as to press with the required force upon E E. Supposing now the handle M down, as in the figure, the handle H is turned, and the bed is carried, by means of the rollers upon which the bed rests, below the frame D D and board I, and thus receives sufficient pressure to deliver the impression. The handle M is now thrown up into the position shown in fig. 15, when (the pressure being thus removed) the bed is easily drawn back again over the rollers, and slides into the position shown in the figure. The frisket is now opened, the impression removed, another plain sheet is then introduced, the frisket shut down, and the handle M is again depressed, when, by means of the handle H, the bed is again rolled through and another copy taken, and so on. There are various forms of these presses; the one described is, perhaps, as simple as can be desired.

Gem en-
graving.

(1098.) *Gem engraving.*—Having described all those kinds of engraving intended for producing multiplied copies on paper, we propose to conclude this article by a concise account of some other kinds of engraving, *viz.*, as gem engraving and die sinking, which is also a species of engraving. In gem engraving, the diamond, which is the hardest of all stones, is cut only with its own dust; in some others emery may be employed. In shaping or cutting rough diamonds, the first thing to be done is to cement two such stones to the ends of two sticks large enough to hold them steadily in the hand, and to rub or grind them against each other till they are brought to the desired form. The dust or powder thus rubbed off is to be preserved, and is employed afterwards to polish them. This is performed with a kind of mill, which turns a wheel of soft iron. The diamond is fixed in a brass tool or dish, is covered with its own dust mixed with olive oil, and is thus applied to the wheel, first on one face and then on another, till the desired polish is produced.

Rubies, sapphires, and topazes are cut and formed in the same way on a copper wheel, and polished with tripoli diluted in water. Other softer stones, as agates, amethysts, emeralds, hyacinths, &c., are cut on a leaden wheel with emery and water, and are polished with water on a pewter wheel, and lapis lazuli, opal, &c., are polished on a wooden wheel. To fashion and engrave vases of agate, crystal, lapis lazuli, or similar stones, a lathe is made use of to hold the vessels, which are to be formed with proper tools; but in engraving the tools are applied to the lathe, and the subject under operation

is held against it by the engraver, the tools being moistened from time to time with diamond dust and oil if necessary, but commonly with emery. To engrave figures or devices on any of these stones when polished, such as seals, &c., a small iron wheel is used, the ends of whose axis are received within two iron cheeks placed upright as in the common lathe, so that they may be brought nearer or set further apart at pleasure, and at one end of the axis the proper tool is fixed by a screw, which will allow the tool to be readily changed; this wheel being put in rotation by the foot, the stone is applied by hand to the tool, its position being changed and ordered as the work to be performed requires.

The tools used by gem engravers are commonly iron, but some are of brass, and generally resembling chisels, gouges, &c.; others are like ferules, to take the pieces of stone out; others flat, &c. When the engraving is finished, it is polished on wheels of hair brushes with tripoli.

(1099.) *Die sinking.*—This is also a kind of engraving Die performed on punches, matrices, and dies proper for striking medals, coins, and counters. The method of proceeding is the same in all these cases, at least the only difference consists in their greater or less relief; this, in coins, being considerably less than in medals, and in counters commonly less than in coins. The engraver in steel usually begins with punches which are in relief, and serve for making the creux or cavities of the matrix and dies; sometimes, however, he begins immediately with the creux, but it is only when the intended work is to be cut very shallow. The figures are designed and moulded in white wax of the size and depth required, and from this model he graves his punch, which is of steel, or of steel and iron mixed in certain proportions; the intended design being formed on this in its soft state, it is then rendered hard by a proper tempering.

The instruments used in this relief engraving are much the same as those wherewith the finishing the work in creux is effected, and are of steel; the principal are gravers of different kinds, chisels, flatters, &c. When the punch is finished, and the proper temper given to it, it is ready for being employed in sinking the matrix, which is effected by blows with a hammer.

The matrix must be a piece of good steel, of a cubic form, whereon the relief of the punch is struck in creux. This steel must of course be rendered as soft as possible by being made red-hot, that it may the more readily receive the impression which is given to it in this state; it is afterwards improved by the graver till the desired effect is produced; it is then hardened, and is fit for use.

Modelling and Sculpture.

(1100.) It is not our intention in this place to treat Moulding of these subjects as branches of the Fine Arts, which has been already done at length in another Division of this Work; our object is simply to describe the mechanical processes which are pursued with a view to produce the desired effect. There are several forms in which statues, busts, &c., are exhibited: first, in plaster of Paris or other material of a similar kind; secondly, in brass, bronze, or other metal; thirdly, in marble or other stone; we may also add, fourthly, in wood. In all these cases, the first process belongs entirely to the artist, who provides himself with a lump of clay with which to model the intended figure, and having first, by a drawing,

Mechanical
Processes.

Manufac-
tures.

sketched a general idea of his work, he proceeds to execute the same in clay of the full size. In this part of the process his tools are of the most simple kind, made of wood or ivory, with their ends pointed, round, square, or diagonal, with which, having by hand reduced the clay to something like what is required, he produces the more minute effects of form and expression. It may be remarked, that if the clay model is large, it must be supported by framework to prevent its bearing wholly on its own base, and the masses of clay must be kept together by a number of small wooden crosses attached to the framework by wires of different lengths dispersed through various parts of the clay.

Making the
mould for
casting.

When the clay model, which we will suppose to be a bust, is finished, it must be moulded or cast, or rather, perhaps, cased, with a covering of plaster of Paris. To effect this, some plaster is made up very thin, not thicker than thin cream, and with this the statue is cased. It is to be observed, however, that, to facilitate the removal of this case afterwards, the principal part behind is separated from the front by the following contrivance: a thin edge of clay is laid along the figure from the head to the base, and the front is first completed up to this ridge of clay, the moulder carefully casting the thin plaster into the recesses in the eyes, ears, nostrils, &c.; a thicker plaster is then thrown on till a thickness of two or more inches is obtained; the ridge of clay is now removed, the edges of the plaster slightly touched with oil, and then the back is covered in the same way till the whole becomes a shapeless lump of plaster of Paris of considerable thickness and weight, and forming externally one solid lump.

This single lump is now separated by a few blows with a mallet and chisel, and the mould thus divided into two parts. The clay figure is then broken out, and the two parts cleaned to remove all the clay from the smaller recesses, and the inside slightly touched with oil in all the more delicate parts. The two halves are then replaced and bound together with cords, and a complete mould thus obtained of the original clay figure. A quantity of plaster is now poured in and rolled about so as to form a thin coating; then more is added, then more, and so on, till a sufficient thickness is given to the internal figure. The mould must now be broken off, an operation which requires great care, in order to avoid destroying any part of the interior figure. This is done with a chisel and mallet, by which piece by piece is removed till the interior figure is produced a perfect copy of the original model.

If the work thus obtained is intended simply for the guidance of the sculptor, this part is now completed, and the operation of the sculpturing proceeds as described below; but if it is intended to obtain from it other cast figures in plaster, another mould, called technically a *safe mould*, must be made. This is formed in detached pieces, something after the manner described for casting brass statues, (Art. 924.) so that after a figure is cast the mould may be removed piece by piece, and then put together again to cast others in the same way. It may be asked, when the object is simply to make plaster casts, why is not this done in the first instance? The reason is that the clay model has not sufficient resistance in it to bear the operation. Copying this model is the work of the sculptor, and by different artists is conducted in different ways as far as regards the removal of the large portion of the block, till an approach is made to the figure; from this last stage the genius and

Sculp-
turing.

talents of the operator must be exercised according to rules altogether independent of mere mechanics. Mechanical
Processes.

The former mode of copying was as follows: a number of small black points were marked upon the model in every principal projection and hollow, to give the distances, heights, and breadths sufficient to copy the model with the greatest exactness. The Ancients, it is said, performed this by considering every three points on the figure as a triangle, which they made in the marble to correspond with the same three points in the model, by trying it with a perpendicular line, or some fixed line, both in the marble and the model.

Our present artists, as we have said, use other methods. According to one, after having by rough measures ascertained that the block is of sufficient size, it is fixed on a basement of stone, or a strong wooden bench called a *banker*, in front of which is a long strip of marble divided into feet and inches. A strip of marble, divided exactly in the same manner, is placed below in front of the model, and a wooden perpendicular rule the height of the work, which is movable from the strip of marble or scale under the model to that under the block of marble which is to be cut. This rule or instrument being first placed on the scale of the model, and the exact distance taken from it to any prominent part, as, for instance, the end of the nose, is then removed to the corresponding position of the other scale, and the workman cuts away the marble to the same distance from the perpendicular at the same height, that is, till he has arrived at that point of the block which is to become the tip of the nose. He then proceeds in the same way with another prominent part, as the top of the head, the chin, &c., till he has fixed all the more prominent or principal parts; he then proceeds to other parts till he has at length obtained a rough figure, containing within it all the other minutiae which remain to be brought out by the more skilful hand of the master.

(1101.) *Machine used by sculptors.*—A more rapid and, perhaps, more exact mode of obtaining the first rough outline has been adopted by some artists. The model and block being arranged on the banker in the same line, a brass frame is placed in front, on which slides a perpendicular, also of brass; this carries a tube through which a rod passes, and which is brought in front of the model, and the point applied to any part of the bust; the point being set, a screw is run down to fix the distance exactly. The instrument is now placed in a corresponding position in front of the block, and the position of the point marked by the end of the rod. A hole is now drilled in the block in this place, till the depth of the hole is such as to allow the instrument to reach by its stop the ruler in front; the exact point in the block is thus obtained. Another point is now taken, and the block drilled in the same way till the whole becomes like a piece of honeycomb; and these parts being now cut away with the chisel, taking care never to remove any part below where the drill has been, the figure in its rough state is fit for the hand of the sculptor.

Another exceedingly ingenious method has been proposed by Mr. Behnes to the Society of Arts, for which he received their gold medal, and which is described in their *Transactions*, vol. xxxvii. This is represented in plate lxxxiii., fig. 1, 2; the former showing the model, and the latter the marble block in the progress of working. The nature of the instrument and operation will be sufficiently obvious by simple inspection: F is what we have described as the banker; S S, fig. 1, 2,

Manufac-
tures.

blocks of stone, to which are securely fixed the semi-circular cast-iron beds E, E; these two beds, *viz.*, under the model and under the block, being made very exactly alike; G, G are cylindric holes in the iron beds, also exactly the same size, to receive the axis of the instrument as represented by the dotted lines; this is retained in its place by a catch, but is removable at pleasure so as to fix the instrument itself in front of either figure. The tube H, which is attached to the axis, receives the tube B of the instrument, and is held in its position by the two clip screws seen in the figure. On the upper part of the tube B is a cap M and a set screw *m*, by means of which the upper part or circle D may be turned in any position, and then fixed by the screw to that position. On the axis D is another clip tube N and set screw *n* for receiving, adjusting, and fixing the small cylindrical tube C; and *d* is a stop adjustable on the arc whereby the instrument after being turned back, as shown in fig 2, may be returned to its position. Q is a triangular socket in which slides the needle P, and *q* is a small set screw or stop to fix its position forward, but allowing its being withdrawn; this turns by means of a ball and socket O screwed firmly at right angles into a cylindrical cavity at the extremity of the lesser cylindrical tube C; this gives the needle containing the gauging point a complete circular motion for all angles less than 90°. The position in any case being taken, the motion of the ball in the socket is prevented by turning the screw *r*. It is only necessary further to add, that the first tube H is fixed in any required position by small studs at its back, not seen in the figure, which are inserted into the corresponding holes in the plate, the front of which is of gun metal securely screwed to the cast-iron beds.

The method of using the instrument is now obvious; the tube H is fixed by inserting its axis into the hole G in the plate under the model, and the studs at its back into the proper holes in the arch, according with any convenient position for the large tube B; this tube is in like manner raised or depressed to any required degree by sliding it in the tube H, and is then made fast by the set screws *h h*; the small tube C and the axis D are now also conveniently arranged for taking any proposed point of the model; the latter is then fixed in its place by the set screw *m*, and its position marked by the adjustable stop *d*, whereby, after being turned back, this tube may be brought again to the same position. Lastly, the needle may be directed to any point of the bust by means of the ball and socket joint, and is then made fast by the screw *r*. The needle being now at its point, the stop *q* is adjusted and fixed, which prevents the needle from advancing, but admits of its being drawn back. The instrument is next removed to the bed under the block, the axis introduced into the hole G, and the studs into the corresponding holes to those in its former position, fig. 1. Every thing remaining as before, except that the needle P has been drawn back, this is now advanced, and the point in the block ascertained on which the operation is to commence, and where the marble must be cut or drilled away till the needle can be advanced to the position marked by the stop *q*; another point is then to be taken, and so on till the block is reduced to the state for receiving the last touches of the master.

On this subject, perhaps, we ought to say but little; we may, however, add, that the sculptor now proceeds to work over his bust or statue with a flat-ended steel tool

called a chisel, the end being about five-eighths of an inch broad. In the naked parts of the statue, and wherever there is a flat surface, he cuts away the rough surface from a given point in a straight line to another point at some distance; he then cuts away the surface from one given point to another exactly parallel to the course his chisel went before; he then cuts the marble in a line at right angles with the former direction of his chisel. He continues to work over the surface in this manner, always cutting the lines parallel to each other, leaving the space of about the eighth of an inch between each course of his chisel. He then cuts away the remaining rough surface, leaving about one-eighth of an inch between each two courses; thus obtaining a beautiful flat surface to his work, which can be obtained by no other means, but may be afterwards varied with the curvatures and indentures of the minor parts at pleasure.

This method of cutting the stone is followed as much as possible in all parts of the work; that is, as much as all the variety of outline and hollows will permit. When the latter are so deep and intricate that they cannot be cut out with small chisels struck by the hammer, drills of different kinds are employed to produce the rough hollows, which are afterwards finished with the hammer and chisel, or by long tools fixed in wooden handles, used by the hand only, without the hammer.

A particular dexterity is required in producing the different characters of the hair with the chisel to make it look light and soft, curled or plain, which is, however, done by the hand of the experienced sculptor with nearly the same effect as by the painter in laying on his colours with the pencil. The finishing of flesh in imitation of the fulness of muscle, the apparent pliability of the softer parts, the greater or less durability of tendon and bone, may also be represented in marble nearly to deception; but to effect this the sculptor must be well acquainted with the structure and appearance of the parts he represents, and accurate in copying the object of his imitation.

The last finish to the marble in the modern practice of sculpture is performed by the use of rasps, and afterwards of files; the best rasps for sculpture are made in Italy, their teeth being cut more sharply than those made in England, at the same time that the ends of these rasps and files are capable of being bent in any form, according to the use for which they are to be employed; if the piece of sculpture is required to have an exceeding smooth surface, the pumice stone is used after the file; and sometimes the whole surface is rubbed or ground carefully over with small pieces of grit stone, accommodated to the various forms of the surface, as to flat spaces, rounds, and hollows of different depths. But the hair in all cases must be finished with the tool; and for this purpose, the edge of the tool must be sharpened with great accuracy and acuteness; and if it is required that the work should be very highly finished, the last edge of the tool must be given by an oiled Turquoise stone. Chisels may be sharpened for the different kinds of work, either on one side or on both, horizontally, diagonally, circular, or pointed. The sculptor uses large square four-footed strong stools with tops, which turn round upon little balls of brass or iron, on which he places the marble statue he works on; his tools are steel chisels of different sizes and lengths, their ends being from an inch broad, and diminishing in succession till they become perfectly pointed. These are worked with an iron-headed hammer, weighing from

Mechanical
Processes.

Method of
using the
chisel.

Manufac-
tures.

two to four pounds, according to the heaviness or lightness of his work. The first tools used in wasting away the marble are strong steel tools, sharpened nearly to a point, which, being struck with a heavy hammer obliquely, knock off the waste marble in much larger pieces than a broader pointed tool would do. The practice of the sculptor also requires the frequent use of the square and compasses, as his own ingenuity may direct.

Miniature
ivory busts.

A very ingenious method of reducing and copying busts and statues (at least if we may judge from the results, for the method itself is not made public) has been lately introduced and practised in London; whereby any large bust or other figure is very exactly copied in miniature in ivory, of one-sixth, one-eighth, or one-tenth of the linear dimensions of the original figure. The exhibitions of these miniature busts, which we have seen, are exceedingly satisfactory; the likeness is most correctly preserved, and the surface and finishing very beautiful. The machine and process employed is a secret in the keeping of the inventor, and we can, therefore, only conjecture what they are; and as these conjectures may be erroneous, we think it better to leave the subject without description than to describe it incorrectly.

Modelling
in wax.

(1102.) *Modelling in wax.*—This may be considered as a branch of sculpture, inasmuch as it affords patterns and examples for very numerous articles of Fine Art in metals. Although, from the nature of the material, no wax model of the Greek or Roman times has come down to us, they must have been almost innumerable during the best Ages of Greece and Rome, judging only from their small figures of divinities in bronze, of which, perhaps, upon an average, every person, rich and poor, might have half a dozen; so that the amount of these small images from patterns of wax would be nearly six times in number of the population of the civilized world at any one period. Wax modelling, besides, is required for the patterns of all goldsmiths and chasers of ornamental work upon a small scale; all the fine medals of the Popes were copied from small models in wax of the most distinguished sculptors. To make the best modelling wax, take two cakes of virgin wax, break them in pieces, put them into a clean pipkin, and the quantity of the smallest hazle-nut of Venice turpentine and about double the quantity of flake white reduced to the finest powder; place the pipkin over a slow fire till the wax is melted, stir the composition together, and it is the best wax which can be used for modelling. Models of different-coloured wax may be made by putting pounded red, blue, yellow, &c., instead of flake white, according to the colour required; the same instruments are used for wax modelling as for clay, viz. wood and ivory nicely pointed. Sculpture in bronze and silver is practised in the same manner by the Moderns as Pliny describes it to have been by the Ancients, and is of three kinds; the subject is either cast from a model, or carved from the solid metal, or otherwise chased from a model upon a flat piece of metal, which is beat hollow on one side to produce the relief, out of which the chaser works the intended figure or figures on the other side. The instruments used in chasing are, for small work, a small hammer with a long elastic handle, which gives the blow a quick and artificial force; also chisels and points, somewhat like those used in sculpture of marble on a smaller scale. The tools for carving in wood are so universally known to carpenters, upholsterers, and the different orders of wood carvers, that the description of them would be useless.

Lens and Speculum Grinding for Telescopes.

Mechanical
Processes.

(1103.) It is well known that the object-glass of an achromatic telescope is composed of two lenses, one of flint glass and the other of plate or crown glass; which, having different refractive and dispersive powers, may be so proportioned in their curvatures that, while from a combination of the two the rays are brought to a focus, the greater dispersion of the flint lens may be corrected by the less dispersive power of the plate, the one being negative and the other positive. The plate is the convex lens; that is, the sum of the reciprocals of the radii must be positive, although one only may be a convex surface; and, on the other hand, the flint must be negative, that is, the sum of the reciprocals of the two radii must be negative; the radii in both lenses being accounted negative when concave, and positive when convex. Moreover, the length of the positive focus of the plate must be to the negative focal length of the flint in the exact ratio of their dispersive powers, in which case the lens becomes achromatic or free from colour.

Grinding
glasses
and specula
for tele-
scopes.
General
principles.

There is, besides, another point to be attended to in proportioning the curvatures of lenses for refracting telescopes, which is what is called correcting the spherical aberration. The refractive power of the glass bends the rays of light falling on or rather entering its surface, according to a certain law; which is such that the sine of the angle at which the ray meets the surface is to the sine of the angle in which it proceeds in the medium in a given and constant ratio while the glass is of the same kind; but it differs greatly in different kinds of glass, and even in different specimens from the same furnace. The same occurs again when the ray, having passed through the lens, arrives at the other surface and passes into air, the ratio here being the inverse of the former. Now the angle at which the ray meets the surface is the angle of the ray with the tangent of the surface, and this is of course different at points of the lens, at different distances from the centre; so that when the lens is of considerable dimensions the actual angles of incidence and refraction are different, and the rays do not all proceed therefore to the same point, as they ought to do for perfect vision. For example, taking any single point in an object, the rays from this single point diverge and fall on every point of the object-glass; they are then, on entering the glass, refracted according to the law above stated, and again on arriving at the other surface, and bent to a focus. But this focus is, for the reason above stated, not an individual point but a succession of points one behind the other; or, if the convergency of the rays be intercepted by a plane instead of a point, we shall have a small circle to represent what ought to be only a single point, and thus a certain degree of indistinctness is introduced into the image; for, the same happening for every individual point of the object, every one will be in part blended with those adjacent to it; and this effect, which is unconquerable in a single spherical lens, is what is known by the term spherical aberration of the lens; but this defect like the former, viz. the chromatic aberration, may be corrected by a double lens formed of two kinds of glass having different refractive powers, or, at least, if it cannot be entirely destroyed, it may be rendered very inconsiderable. The reason why it cannot be wholly corrected is, that the curvatures requisite to effect it depend upon the indices of refraction, and these indices being different for the different coloured rays, the curvatures that will correct the red ray, for

Manufac-
tures.

instance, will not correct the violet, and the converse; opticians, therefore, correct the mean or green ray, leaving the others to their fate, and consequently the one is over, and the other under corrected.

A similar imperfection arises in the first correction we have pointed out for achromatism; this arising from a want of uniformity in the coloured spaces of the spectra in glass of different dispersive power, some of the colours in one spectrum bearing a very different ratio to the whole to what happens in the other; the length of the violet, for example, bearing a much greater ratio to the whole length of the spectrum in one than in the other, and the same more or less for all the colours, so that the curves which correct the one will not correct the other. This subject is treated of with great precision in our Treatise on OPTICS, and will not, therefore, require any theoretical illustration in this place, where we only propose to describe the mechanical processes by means of which that theory is reduced or applied to practice. At the same time, merely practical rules for grinding, polishing, &c. would be useless, without also giving rules for determining the proper radii of the tools; for the best workmanship would be thrown away upon wrong curvatures, as the most profound theory would be without perfect surfaces. Referring, therefore, the reader for every point connected with the theory of the telescope to our Treatise on OPTICS, we shall proceed to give simple practical rules for determining the curvatures, and afterwards a description of the mechanical processes by which these curvatures are to be obtained.

Method of
finding
the refrac-
tive index.

(1104.) *Determination of the refractive index.*—Before the first step can be taken towards the construction of a refracting telescope, the index of the refractive power of the plate and flint glass intended to be employed must be determined. This may be done in different ways, viz. by employing small prisms of the glass in an instrument called a goniometer, by measuring the focal length of a line of known curvature, and by other means described by different writers; but that of measuring the focal length is by far the most simple, and most consistent with the practical optician's means of measuring, and which, therefore, we describe in this place from an article on this subject by Mr. Barlow, given in the *Phil. Trans.* for 1827. The author observes, "The following method of determining the index of refraction, by means of a lens, is not given as new; it has, on the contrary, been long practised; but as it forms the foundation of the method for determining the dispersive ratio, and will occupy but a few lines, I shall be excused for introducing it into this Paper.

It is simply this: since by knowing the radii of curvature of a lens, and its index of refraction, we may compute the focal length; so, conversely, by knowing the radii and measuring the focal length, we may compute the index of refraction. The method which we employed for measuring the focal length of a lens was as follows: a tube about two inches and a half in diameter, and which exactly measured ten inches from the back of the lens to its other extremity, was fitted with a draw tube of the same length, graduated to inches and tenths; and which, by means of a vernier, might be read to the hundredth of an inch. This was fitted with a positive eye-piece, which was adjustable to bring the cross wires exactly into its focus, and the graduations above mentioned commenced from this point or stop. A board about two feet square, covered with black crape, and having a clean circular piece of card

paper, with fine cross lines upon it, was placed at a convenient measured distance from the lens, and then the draw tube was adjusted till we had the focus exactly coincident with the cross wires. This is easily ascertained by moving the eye a very little upwards and downwards. Then, when the image does *not* fall on the wires, this motion of the eye will produce an apparent motion between the cross wires in the telescope and those on the card; but when they are coincident, then, however the eye may be moved, the image and the cross wires will be at rest. This being determined, the focal length for this distance of the object is read off as above described. Let this be f , the distance d , radii r, r' , and index $1 + a$; then, by a simple inversion of the well-known formula for the focal length of a lens, we have

$$a = \frac{r r'}{r + r'} \left(\frac{1}{f} + \frac{1}{d} \right).$$

But as for these experimental purposes we made the radii equal, or $r = r'$, this formula becomes simply in this case

$$a = \frac{r}{2} \left(\frac{1}{f} + \frac{1}{d} \right) \dots \dots \dots (1.)$$

Phil. Trans. 1827.

It may be well to describe in this place the method of measuring the tool which is requisite in this proceeding. The lens for this purpose being convex, the tool is necessarily convex. A piece of thin glass was brought on its edge to this curvature nearly by cutting it with the usual shears, or by other means; it was then ground on its edge in the tool till it took the exact curve. The question then is, from this short segmental arc of a circle of 10, 20, &c. to 100 and 200 inches radius, to determine what that radius is. To effect this the segment was laid flat on a long plain board or table, and while held down three pins were pricked in the board to touch the curve, one at each end, and the other in the middle. One end pin was then removed, the glass gauge slipped on in contact with the other two, till one of these was near the end, the pin just removed was then stuck in, the second pin removed, the glass slipped on again, and the last pin again inserted, till the arc of the circle, which on the gauge was only three or four inches, was lengthened ten, twelve, or more times; then, by carefully measuring the subtending chord and versed sine, the radius of curvature was obtained to the greatest accuracy. As an example of the application of the formula given above, let us suppose that the small lens used in the index instrument was exactly 10 inches, that the distance of the object from the lens was 200 inches, and the measured focal length was 11 inches; then, by the formula,

Method of
measuring
the tools.

$$\begin{aligned} a &= \frac{10}{2} \times \left(\frac{1}{11} + \frac{1}{200} \right) \\ \frac{1}{11} &= \cdot 0909 \\ \frac{1}{200} &= \cdot 0050 \\ &\quad \cdot 0959 \\ \frac{10}{2} &= 5 \\ a &= \cdot 4795 \text{ index.}^* \end{aligned}$$

* The proper index is $1 + a$, but we shall in what follows call this decimal part only the index, according to common usage.

Manufactures.

As another example, let the focal length be 10·5, and distance of object 200 inches as before.

Then

$$a = \frac{10}{2} \times \left(\frac{1}{10 \cdot 5} + \frac{1}{200} \right)$$

$$\frac{1}{10 \cdot 5} = \cdot 0952$$

$$\frac{1}{200} = \cdot 0050$$

$$\cdot 1002$$

$$\frac{10}{2} = \frac{5}{1}$$

$$a = \cdot 5010 \text{ index.}$$

Nothing can be desired more simple than this calculation, nor does any practice require a more exact method of determination.

Method of finding the dispersive ratio.

(1105.) *Practical method of finding the dispersive ratio between two pieces of glass.*—The following method of determining the dispersive ratio was first proposed by Mr. Barlow, in the article above referred to; but, in a note, the author states that a similar principle was suggested, but not at that time published, by Sir John Herschel for correcting any slight defect of colour. The views are dissimilar and independent of each other, and the resulting equations are also different but equivalent.

The instrument employed for this purpose is similar to that above described for determining the index, except that the tube, instead of being only 10 inches in length, consists of three joints, one 20 inches, and two others 10 inches each, the draw tube being about 14 inches long, (graduated as before;) so that the length may be conveniently varied between 20 and 50 inches. The cell, which carries one of the lenses at the extremity of this tube, screws inside flush with the tube itself, and will thus admit another tube about 20 inches long to slide over it; at the extremity of the latter is another cell for carrying the plate lens.

This exterior tube is moved over the other by means of a tangent screw and handle, with Hook's universal joint, as in the adjustment of transit and other instruments. Moreover, the exterior tube being opened for the space of two inches, and the interior tube graduated, the distance of the two lenses from each other may always be read off to the hundredth of an inch.

The instrument being thus described, the method of using it, and the principle on which the determination rests, will be readily understood. It is well known that in order to produce achromatism in an object glass, it is requisite that the focal lengths of the two lenses be to each other in the ratio of their dispersive powers; that is, the ratio of the dispersive power of the flint being to that of the plate as 1 : d , the focal length of the flint must be to that of the plate also as 1 : d , the two lenses being in contact.

If, therefore, we have two lenses, viz. a concave flint and a convex plate, in which the focal length of the latter bears a greater ratio to that of the former than 1 to d , we must open the two lenses from each other till the required ratio is obtained, when the object will be colourless, and therefore conversely, when the image is colourless, we shall be sure that the ratio of the focal lengths will be that also of the dispersive powers.

To illustrate this a little more particularly, let f, f' be the focal lengths of the plate and flint lens, and let δ be the distance of the lenses when the image is colourless.

Then, first, it is obvious, that the effect will be the same as if we had a plate lens in contact with the flint, which had for its focal length $f - \delta$, but the actual quantity of its dispersion that due to the whole focal length f ; that is, the same as a plate lens of focal length $f - \delta$,

and whose dispersive power = $\frac{fd}{f - \delta}$.

And since in this state the image is colourless, it follows that

$$f' : f - \delta :: 1 : \frac{fd}{f - \delta}.$$

And therefore d , which is the quantity sought, is found from the equation

$$d = \frac{(f - \delta)^2}{ff'} \dots \dots \dots (2.)$$

The lenses employed were about 2½ inches in diameter, equally convex in the plate, and plano-concave in the flint; their focal lengths varying in the plate and crown from 9½ to 10½ inches, according to their respective refractive indices, and in the flint from about 10 to 11½ inches.

The flint lens, as will have been observed from the preceding description, is placed in the interior tube, and the plate in the exterior; and if, when the two interior faces of the lenses are in contact, the index does not read zero, its actual reading is recorded; and ultimately, the index reading when the image is colourless is corrected by this quantity.

This preliminary being attended to, the manner of conducting the experiments is as follows.

Fix up the black board with the circular white spot, as already described, at a convenient distance, and in a good light, directly opposite the tube properly mounted on its stand.

Let the two lenses be placed nearly in contact, and suppose the length of the tube reduced to about 20 inches. Now move the plate lens gently forward by means of the handle and screw, the eye being placed at the eye-glass, and the image of the circular spot will, after a time, begin to appear in the field of the telescope, having a bright and strong violet spot in the middle; at this time a very little further motion in the plate lens will give a distinct image of the object, but encircled by a strong violet shade.

If now the tube be lengthened to about 25 inches, and the experiment repeated by closing the glasses, the violet spot in the middle, and the circular ring when the focus is obtained, will have changed to a fine blue. If again we lengthen the tube considerably, that is to nearly 50 inches, we shall find by repeating the experiment, that is, by closing still more the two glasses, that the circular spot before the image is formed, and the surrounding atmosphere when the focus is obtained, will be red, orange, or yellow; and between these extremes a focal length will be found where the circular spot in the middle will lose all distinguishing colour, showing itself a bright white, and when in the focus the image will be colourless, although surrounded by a visible atmosphere, principally proceeding from a want of spherical correction.

At this time the glasses are corrected for dispersion, and the compound focal length measured from the back of the flint, and the distance of the glasses must be accurately read off; and with these data the dispersion may be obtained by the formulæ already given, viz. :

Mechanical Processes.

Manufactures.

$$d = \frac{(f - \delta)^2}{ff'}$$

In this expression f is the focal length of the plate lens for the given object, and f' the focal length of the flint for parallel rays. The former may be found by direct observation with the index instrument, as already described, but the latter is best determined by means of the compound focus; that is, calling the compound focus f'' , we shall have

$$\frac{1}{f'} = \frac{1}{f''} - \frac{1}{f - \delta};$$

and f' being thus determined is to be employed in the preceding formula.

As an example: suppose the compound focus measured from the flint to be 34.89 inches, the focal length of the crown lens 9.85 inches, and the distance between the lenses 1.41 inch.

First,
$$\frac{1}{f'} = \frac{1}{38.89} - \frac{1}{8.44};$$

whence
$$f' = 11.13 \text{ inches};$$

then
$$d = \frac{(f - \delta)^2}{ff'} = \frac{8.44^2}{9.85 \times 11.13} = .649,$$

the dispersive ratio sought.

Formulae for computing the curves.

The index of refraction of the plate and flint glass being thus determined and denoted by a and a' respectively, and the dispersive ratio by d , the proposed focal length of the telescope by f'' , then all the other conditions may be computed as follows:

$$f = f'' (1 - d) = \text{focal length of plate.}$$

$$f' = f'' \left(\frac{1 - d}{d} \right) = \text{focal length of flint.}$$

Assume $1 : q'$ to represent the ratio of the radii of the flint surfaces which may be taken at pleasure, (at least within practical limits,) then

$$\begin{aligned} r'' &= f' a' \left(\frac{1 + q'}{q'} \right) = \text{inside radius} \\ r''' &= f' a' (1 + q') = \text{outside ditto,} \end{aligned} \quad \left. \begin{array}{l} \\ \end{array} \right\} \text{flint lens.}$$

Find
$$b = \frac{a'}{a + 1}; c' = \frac{(a' + 1)f'' q'}{a' f'' - r''}$$

$$p = \frac{(c' + 1)^2}{(b c' + 1)^2} \times \frac{c' + 2 - b}{c'} \times \frac{a d q'}{q' + 1}.$$

Enter the following Table with this value of p , or the nearest to it, and take out the corresponding value of q :

p .	q .	p .	q .	p .	q .	p .	q .
1.15	.374	1.40	.683	1.65	.972	1.90	1.29
1.20	.446	1.45	.739	1.70	1.03	1.95	1.36
1.25	.506	1.50	.798	1.75	1.09	2.00	1.43
1.30	.568	1.55	.855	1.80	1.16	2.05	1.50
1.35	.625	1.60	.913	1.85	1.22	2.10	1.58

Then
$$\begin{aligned} r &= f a (q + 1) = \text{radius 1st surface} \\ r' &= f a \left(\frac{q + 1}{q} \right) = \text{radius 2d surface} \end{aligned} \quad \left. \begin{array}{l} \\ \end{array} \right\} \text{plate lens.}$$

As we are aware that many practical opticians, as well as some amateurs, feel considerable distaste for algebraical formulæ, we will endeavour to illustrate the rules as above expressed by an example at length.

Let it be proposed to make a refracting telescope 80

inches focus, or $f'' = 80$; the index of the plate having been found to be $a = .515$, of the flint $a' = .600$; the dispersive ratio $d = .66$; and let us choose the ratio $1 : 10$ or $q = 10$, for that of the radii of the curvatures of the flint lens.

Then the first two formulæ in words are as follows:

1. Subtract the dispersion from unity, and multiply the remainder by the proposed focal length of the telescope; the quotient will be the value of f , or focal length of the plate lens.

$$\begin{array}{r} 1.00 \\ .66 \\ \hline .34 \\ 80 \end{array}$$

$f = 27.20$ the focal length of plate.

2. Divide this by the dispersion, and the quotient will be the focal length of the flint, or

$$f' = \frac{27.20}{.66} = 41.21 \text{ inches}$$

To find the radii of the flint surfaces.

3. Multiply the index of the flint by the focal length of the flint lens, and that product by 11, viz. $(q + 1)$; this gives

$$r''' = 6 \times 41.21 \times 11 = 271.9 \text{ outside curve of flint.}$$

$$r'' = \frac{271.9}{10} = 27.19 \text{ inside curve of flint.}$$

We have now determined all except the radii of the plate lens; and the steps here are rather more complicated: we will, however, endeavour to give them in words, viz.

1. Divide the index of the flint by the index plus 1, and call the quotient b . In our case, therefore,

$$b = \frac{.6}{1.6} = .375.$$

2. Multiply the index of the flint plus 1 by the focal length of the telescope, and again by the ratio q ($= 10$) of the flint surfaces, and divide the number thus obtained by the following divisor, viz., From the product of the flint index into length of telescopic focus subtract* the outside radius of the flint; call the quotient c' ; that is, in our example,

$$\begin{array}{r} a' + 1 = 1.6 \\ f'' = 80 \\ \hline 128.0 \\ q = 10 \\ \hline 1280 \text{ dividend.} \end{array}$$

$$\begin{array}{r} a' = .6 \\ f'' = 80 \\ \hline 48 \\ r''' = 271.9 \\ \hline 319.9 \text{ divisor.} \end{array}$$

$$c' = \frac{1280}{319.9} = 4.$$

Lastly. Divide $c' + 1$ by $b c' + 1$, and square the quotient.

Divide c plus 2 minus b by c' .

Divide the product of a (the plate index), d (the dispersion), and q' (the ratio $= 10$), by $q' + 1 = 11$.

* The quantity being negative, the subtraction becomes essentially addition in this example.

Manufac-
tures.

Then these three quotients multiplied together give the value of p .

$$\text{Here } \left(\frac{c' + 1}{b c' + 1} \right)^2 = \frac{25}{6 \cdot 25} = 4 \cdot 0$$

$$\frac{c' + 2 - b}{c'} = \frac{5 \cdot 625}{4 \cdot 0} = 1 \cdot 4$$

$$\frac{a d q'}{q' + 1} = \frac{3 \cdot 393}{11} = 8 = 3 \cdot 1 \text{ nearly.}$$

$$\text{Then } p = 4 \cdot 0 \times 1 \cdot 4 \times 3 \cdot 1 = 1 \cdot 75.$$

The nearest corresponding value in the Table of $q = 1 \cdot 09$. Multiply now q plus 1 by the focal length f and index a of the plate for the front radius of the plate lens, and then that product by $q = \cdot 972$, for the radius of the second surface.

$$\begin{array}{r} \text{That is } q + 1 = 2 \cdot 09 \\ a = \cdot 515 \\ \hline 1045 \\ 209 \\ \hline 1045 \\ 1 \cdot 07635 \\ 27 \cdot 2 \\ \hline 215270 \\ 753445 \\ \hline 215270 \text{ inches radius front surface.} \\ 29 \cdot 27 \end{array}$$

$$\text{And } \frac{29 \cdot 2}{1 \cdot 09} = 27 \text{ inches radius second surface.}$$

We have thus all the curves proper for a telescope of 80 inches focus, with glass of the indices and dispersive ratio above stated.

Plate lens	front surface	271 \cdot 9	convex.
	second surface	27 \cdot 19	convex.
Flint lens	contact surface	27 \cdot 61	concave.
	back surface	28 \cdot 4	concave.

Grinding,
polishing.

(1106.) *Practical operations of grinding.*—The requisite curves being thus determined, tools must be provided of the same curvatures, but reversedly, that is, a concave tool for the convex surface, and a convex for the concave. These tools are made of brass, about an inch or an inch and a half thick, and eight, ten, or twelve inches in diameter, with a piece left at the back, in which a coarse thread can be tapped for the purpose of fixing them to work the glass. Each tool ought to have its fellow, so that by grinding the two together the most perfect spherical figure may be obtained. Two pieces of brass, of the thickness above stated, are cast to wooden patterns nearly of the curvature required; they are then, by means of the screw, tapped in the piece at the back, attached to the mandril of a lathe, brought to a good surface, and to nearly the proper curvature. The two, that is, the convex and concave tool, are now worked together with coarse emery till the two surfaces touch each other in all parts, in all positions, when they must necessarily be both perfectly spherical, for no other curve surfaces possess this property of universal contact.

In the workshop is a cast-iron pedestal about three feet and a half high, at the top of which there is a screw, and upon this the tool is secured by the thread tapped in the piece of brass left at its back, and is thus in a condition to commence the grinding. The piece of glass to be ground, being first cut roughly round by the diamond and a pair of optician's shears, is to be fixed

on a handle by means of pitch, that is, the pitch is made sufficiently warm to be quite plastic; it is then attached to the handle, and the glass laid on and compressed, and moved by the hand till it becomes central; when cool, the pitch will have a strong attachment to both. A quantity of coarse emery and water is now smeared over the surface of the tool, and the glass worked in it till all the outside part (if a concave lens) is ground away so that the lens has taken up the required spherical figure. A finer emery is now employed, and greater caution observed to improve the first rough surface; then again a still finer sort, till at length the most complete contact is obtained between the glass and the tool in all and every part of the surface.

The next step is the polishing, which requires the utmost care, not only to get the polish perfect, but also to avoid in this process destroying the figure given by the last. For this operation all the emery is washed out of the tool, and a piece of thin felt or cloth is spread on its surface, and on this a quantity of polishing putty. The workman then proceeds as in grinding, but using great precaution with respect to the degree of pressure he gives, and after some hours' work a perfectly polished spherical surface will be obtained. This being done, the workman by a smart blow, dexterously applied at the back of the glass, disengages it from the pitch on the handle; he then again warms the pitch and attaches the polished side, and works over the other surface on a tool already prepared of proper curvature, and which being ground and polished in the same way, the lens is again removed from the handle, and is thus far finished.

The next step is what is called centring. We will suppose the lens to be convex on both sides; the centring is to give to the lens such a figure that the axes of the two spheres, of which the surfaces are segments, shall be in the same right line; for this continuation of the two axes is supposed in the calculation for curvatures, and upon the perfect centricity of the lenses much of the beauty of the performance of the telescope depends. The centring is effected by attaching the lens by means of pitch and a chuck to the mandril of a lathe, and while the pitch is still warm enough to be pliable, the position of the lens is changed by a pressure of the hand, till, by revolving the mandril as in turning, any object seen through the edges of the lens, or any object seen by reflection on its outer surface, remains steady to the eye during the revolutions. If this is not the case at first, the workman by practice judges what is wanted, and he either lowers or raises the lens on the pitch, or inclines it a little more or less, till by repeated trials the objects seen, both by reflection and refraction, remain stationary during the rapid revolution of the lathe; he then concludes that the lens is fixed centrally, that is, that the two axes coincide, and it only remains to cut it down to a perfect circle.

To effect this, the lens is left on the mandril till the pitch is quite hard. A man or boy now turns the lathe with his foot very rapidly, and being provided with a sort of tin pan and plenty of coarse emery, he applies this at a fixed distance from the centre of the lens, so that the parts most distant from the centre rub pretty strongly against it; by this means these prominent parts are soon reduced. He then approaches his tool a little more, and thus reaches the next projecting parts of the circumference, and so on till he has ground the rest of the prominent parts down, and produced a most perfect circle, which must, when the lens is properly cen-

Mechanical
Processes.

Polishing.

Centring.

Manufac-
tures.

tred, be of equal thickness all round. The lens is now finished, and is washed with spirit of wine, &c. to remove any remnants of pitch, and carefully laid aside till wanted. Precisely the same process is followed with the other lens, but this being concave is of course worked on a convex tool; in every other respect the operation is the same. Both being finished and reduced to exactly the same diameter, their proper surfaces are placed together, and are in this form introduced and secured in a brass cell made to receive them, the size of which must be such as, while it prevents any motion between the two glasses, must not be so tight as to pinch them in any respect, for the least pressure produces a flexure in the lens and totally destroys that accuracy of performance so essential in refracting telescopes, particularly those employed for astronomical purposes.

Grinding
lenses by
machinery.
Pl. lxxxiv.
Fig. 1, 2.

(1107.) *Grinding and polishing by machinery.*—Our best opticians never think of applying machinery for grinding the lenses of the larger and finer telescopes, though we are much inclined to believe that it might be done to advantage; but for grinding common magnifying lenses, such as spectacle glasses, and those for common pocket telescopes, &c., a horse mill is sometimes employed, and some hundreds of spectacle glasses all ground at once. Mr. William Gilbert, 148, Leadenhall-street, had a mill of this sort in his manufactory at Woodford, in which four hundred or more spectacle glasses might be ground at the same time. In these cases the tools are made rather broader than for common hand grinding, and thirty, forty, or even seventy small lenses, or pieces of glass which are to be lenses, are fixed by pitch side by side over the whole surface of one tool, and this tool thus filled is placed on the top of a fixed axle, or to one to which a circular motion is given by the mill, and twenty or more such axles may be revolving at the same time. If we suppose these to be for convex glasses, they must of course be placed on a convex tool, and over them is laid a proper concave tool, the centre of which is attached freely and eccentrically by a crank to the end of a descending vertical axis, which is also driven by the horse mill in an opposite direction to the former. The mill being now put in motion and emery supplied as in hand grinding, the upper tool is made to roll and revolve over the lower eccentrically, while the lower one itself is revolving centrally with a slow motion, so that every part passes under the upper tool, and all the lenses, after a short time, are found reduced to their proper figure, and are then polished; after which they are turned, and in like manner ground and polished on their other side. The crank to the descending axis is so managed that any one tool may be easily disconnected, and may be made to work more or less eccentrically at pleasure.

The above general description will be better understood by referring to fig. 1, 2, plate lxxxiv. in which one tool is represented as grinding and the other as polishing. The central axle is driven, as we have said, by a horse mill. This axle carries two drums, A, B; G E are two iron axles passing through collars in the frame of the mill as represented in the figure, and are driven by bands passing over the drum and pulleys on the axle. These axles, at their lower end, pass through circular holes in the pieces of metal F, F, in which they turn freely till connected by the locking pin *a b*, *a' b'* with the axle. Thus far both sides agree; but now we have some difference to describe. In fig. 1, an iron bar passes through a block of iron attached to the centre

piece F, which bar is bent at its end into the spring C, of the form shown in the figure. The tool H is screwed on the fixed axle A, passing through a heavy collar K, in which, by means of the strong set screw B this may be elevated or depressed at pleasure. At the further angular end of the spring C is a recess or socket, into which is entered the end of the spindle, represented as screwed into the running tool R, which by this means presses the tool or runner down upon the fixed tool; the proper degree of pressure being adjusted by raising or lowering the axle A, and the proper degree of eccentricity is given to the spring bar by sliding it in its collar, and there fixing it by its set screw S. This pressure is such, however, as allows the workman at any time to raise the spring by his hand, and thereby to remove the tool. The action of the locking bar will be readily understood without any particular description; by a smart blow at *b* with a mallet the connection between the axle and collar is broken, and by a blow at *a* the connection is as readily established.

Mechanical
Processes.

On the other side the tool is represented as polishing, the lenses being cemented upon the lower tool. Here the action of the locking bar is the same as already described; but the bar which in the other figure is bent into the spring form is here terminated by a ring, into which the axle of the running tool is inserted, so that only the weight of the tool acts. The lower tool also, in this case, revolves by means of a strap passing over the lower drum and pulley, but this band being crossed the two axles revolve in opposite directions; they are also placed a little eccentric with regard to each other as represented in the figure.

We have only shown two axles, or two pairs of tools; but the mill consists of a square frame, on three sides of which several such axles as are here represented are working at the same time by the labour of one horse, and requiring only the attendance of one man to grind some hundred glasses. The writer has seen four hundred small lenses under operation at one time. This ingenious piece of mechanism is the invention of Mr. William Gilbert, of the firm of Messrs. Gilbert, opticians and mathematical instrument makers, 148, Leadenhall-street.

(1108.) *Grinding specula for reflecting telescopes.*—As we thought it necessary to preface our description of grinding lenses by the rules necessary for computing the proper curves, so also here it is considered to be requisite to state a few particulars relative to the best composition for speculum metal, and the caution which is required in the casting. The specula of reflecting telescopes are generally composed of thirty-two parts of copper and fifteen of grain tin, with the addition of two parts of arsenic to render the composition more white and compact; but the Rev. Mr. Edwards, in the *Nautical Almanack* for 1797, has detailed a variety of experiments on this subject; he found that adding one part of brass and one of silver to the above composition, and using in it only one part of arsenic, a most excellent metal is obtained, which is the whitest, hardest, and most reflective of any he ever saw. The superiority of this composition has been completely proved by the excellence of the instruments made by this gentleman, which are said to have excelled all others in brightness and distinctness; but, unfortunately, metals of this composition are exceedingly difficult to cast as well as to grind and polish, and for this reason they are not so commonly used as could be desired.

Specula.
Composi-
tion.

The following directions for casting are given by Sir

Casting.

Manufac-
tures.

D. Brewster, in his edition of Ferguson's *Lectures*. After the flasks of sand are prepared, and a mould made for the metal by means of a wooden or metallic pattern so that its face may be downwards, and a few small holes left in the sand at its back for the free egress of the included air, melt the copper in a crucible by itself, and, when it is reduced to a fluid state, fuse the tin in a separate crucible and mix it with the melted copper by stirring them together with a wooden spatula. The proper quantity of powdered arsenic, wrapt up in a piece of paper, is then to be added, the operator holding his breath till the fumes are completely dissipated, and when the scoria is removed from the fluid mass, it should be poured out as quickly as possible from the crucible into the flasks. As soon as the metal is become solid, it should be removed from the sand into some hot ashes and coals for the purpose of annealing it, and where it ought to remain till it is cold. The ingate is then to be removed from the metal by means of a file, and the surface of the speculum ground upon a common grindstone, till all the imperfections and asperities are taken away. When Edwards's composition is employed, the copper and tin should be melted according to the preceding directions, and when mixed together should be poured into cold water, which will separate the mass into a number of small particles, which are then to be collected and put into the crucible with the silver and brass. After they have been melted together in a separate crucible, the proper quantity of arsenic is then to be added, and a little powdered rosin thrown into the fluid metal before it is poured into the flasks.

Difficulties
in casting
large spec-
ula.

For the smaller kind of specula these directions may be successfully followed; but in the larger sort great difficulty is encountered, and unfortunately a more debased metal must be employed. Sir William Herschel, as is well known, cast a speculum for his forty-foot reflector of four feet diameter, the weight of which was nearly half a ton; but in this the proportions of tin and copper were about as one to three. Lord Oxmantown has, perhaps, taken a greater part than any other person besides Sir William Herschel in attempts to produce very large reflectors, and has erected for the purpose not only a proper foundry for casting, but also a steam-engine of four-horse power for grinding them; and some useful remarks are given by this ingenious Nobleman on the subject, in Brewster's *Journal* for 1830, vol. ix. He there remarks, "I will endeavour to put the reader in possession of the difficulties he would have to encounter, were he to proceed to construct a large telescope in the common way, and the defects he would probably find in the instrument when finished. He would of course first proceed to cast the metal, and as earthen vessels would not be sufficiently capacious, he would employ either iron ones or reverberating furnaces. If he tried iron vessels before a large quantity of speculum metal (for instance, three or four hundred weight) was raised to a proper heat for casting, he would find that the metal had imbibed some of the iron and was injured, or perhaps, if he were less fortunate, and the fire had been a little mismanaged, that the speculum metal had promoted the fusion of the iron, and thus passed out through the crucible. The reverberating furnace would then be resorted to, and much difficulty would occur in combating the continual change of the quality of the metal from the exposure of so large a surface to the action of the flame. However, the metal once cast, the next process is to anneal it; and he would then find

the speculum would fly to pieces before it was cool, unless the alloy made use of was less bright, less white, and in every respect inferior to the best speculum metal. The next process is to grind the speculum, which, though laborious, does not require much exactness; and, lastly, to polish it, which every one knows is attended with great difficulty. Making a proper estimate of the success likely to be obtained after a great number of abortive attempts, a metal would be completed having a tinge of yellow, deeper in proportion to its size, with perhaps a defective polish, and certainly a figure by no means perfect." Such are the difficulties which attend the casting and completing a large reflecting speculum, and to avoid some of them an inferior metal is had recourse to. Dr. Pearson, in his *Practical Astronomy*, states, that the proportion of tin to copper used by Sir William Herschel for his twenty-foot telescope, was tin 7.75 copper 20, an alloy certainly extremely low, and the metal of the forty-foot was still lower. The defects, therefore, Lord Oxmantown observes, common to all very large specula hitherto constructed may be thus stated: a defective metallic composition ill suited either to receive or retain a polish, or to show objects of their proper colour and brilliancy; a want of sufficient stiffness in proportion to their weight to enable them to retain their figure with that great degree of exactness necessary; and, lastly, a want of as perfect a polish and figure as has been given to smaller specula. The author then proceeds to describe the means he had recourse to in order to obviate these difficulties, which consisted of making the specula with back ribs and flanches, of plating copper with pieces of speculum metal soldered upon them by tin, &c.; but as the description would extend to too great a length, and the completion is not given, we must be content to refer those who are desirous of understanding the process for telescopes of the large size to the Paper in question, and shall proceed to explain the steps necessary to be followed in grinding and polishing metals of a more common size.

(1109.) *Grinding by hand.*—The metal being cast and prepared by the common grindstone for receiving its proper figure, the gauges and grinding tools are to be formed in the same manner as for lenses, as already described, the radius of the gauges being always twice that of the intended focal length of the speculum. In addition to the convex and concave brass tools, which should be only a little broader than the metal itself, a convex elliptical tool of lead and tin should also be formed with the same radius, so that its transverse may be to its conjugate diameter as ten to nine, the latter being exactly equal to the diameter of the metal; on this tool the speculum is to be ground with flour emery in the same manner as lenses, with circular and cross strokes alternately, till the surface is freed from every imperfection and has taken the true spherical figure. It is then to be worked with great care on the convex brass tool with emery of different degrees of fineness, the concave tool being sometimes ground on the convex to keep them to a proper radius, and, when every scratch and appearance of roughness is removed from the surface, it will be fit for receiving the final polish.

Before the speculum is brought to the polishing tool, it has been the practice to smooth it on a bed of hones, covered with a number of grooves at right angles to each other, and about the thirtieth of an inch broad and deep. This additional tool is indeed absolutely necessary when silver and brass enter into the composition

Processes.

Grinding
and polish-
ing by
hand.

Polishing
specula.

Manufac-
tures.

of the metal, in order to remove the roughness which will always remain after the finest emery has been used; but when these metals are not ingredients in the speculum, there is no occasion for the bed of hones; and Sir D. Brewster observes, in his edition of Ferguson's *Lectures*, that he has attained as fine a polish as it is possible to have without the intervention of this tool. Mr. Edwards does not employ any brass tool in his process; but transfers the metal from the elliptical leaden tool at once to the bed of hones, which certainly simplifies the process; but there is some doubt in Sir D. Brewster's mind if any improvement is thus effected. As a bed of hones is more likely to change its form than a tool of brass, it is certainly of great consequence that the speculum should have as true a figure as possible before it is brought to the hones; and this figure may certainly be better obtained on a brass tool, which can always be kept to its figure by its pair tool, than an elliptical block of lead, and we are certain that, when the focal length is to be very exactly of a given length, the brass tool is the most certain. Mr. Edwards, however, states that these tools are not only unnecessary but detrimental; in which opinion, however, Sir D. Brewster does not coincide. He observes, "That Mr. Edwards found them unnecessary, we cannot doubt, from the excellence of the specula he formed without their assistance; but it is inconceivable how the tool can be in the least detrimental. If the mirror is ground upon twenty different tools before it is brought to the bed of hones, it will receive from the last of these tools a certain figure which it would have received even if it had not been ground upon any of the rest; and it cannot be questioned that a metal wrought upon a pair of brass tools is equally, if not more, fit for the bed of hones than if it had been merely ground on a bed of hones."

When the metal is ready for polishing, the elliptical leaden tool is to be covered with black pitch about one-twentieth of an inch thick, hardened a little in the warmer weather with a little rosin, and the polisher formed either with the brass tool, or with the metal itself. The colcothar of vitriol should then be triturated between two surfaces of glass, and a considerable quantity of it applied at first to the surface of the polisher. The speculum is then to be worked in the usual way upon the polishing tool till it has received a brilliant lustre, taking care to use no more of the colcothar if it can be avoided, and at all events the least possible quantity of it after the first. When the metal moves stiffly on the polisher, and the colcothar assumes a dark muddy hue, the polish advances with great rapidity, the tool then grows warm, and would probably stick to the speculum if the motion were discontinued for a moment. At this stage of the process, therefore, it is necessary to proceed with great caution, breathing continually on the polisher till the friction is so great as to retard the motion of the speculum. When this happens, the speculum is to be slipped off the tool at one side, cleaned with soft leather, and placed in a tube for the purpose of trying its performance, and if the polishing has been conducted with care, it will be found to have its true figure.

In polishing the small speculum for his Newtonian reflectors, Sir W. Herschel always employed two or more tools considerably larger than the speculum to be polished, but he did not use them till after the speculum was made nearly flat with emery upon a small tool of lead. These tools or beds of hones should not

VOL. VIII.

be less than six inches in diameter, and they are not to be considered as completed till the speculum can be first highly finished upon one of them, and afterwards be applied to another without experiencing any change of figure. The last six strokes should be performed in the direction of the longer axis of the ellipse; when the speculum is thus brought to a perfect figure, it must be polished upon a pitch polisher of a circular form, whose diameter is but one-tenth greater than the transverse axis of the speculum. Ferguson's *Lectures* by Brewster.

(1110.) *Grinding specula by machinery*.—Several different means have been devised for grinding and polishing specula by machinery, but our limits will not admit of our entering upon them at great length. A machine for this purpose, on a very large scale, has been constructed under the direction of Lord Oxmantown, which is worked by a four-horse power steam-engine, the operation of which is exceedingly simple. A drawing and description of this machine is given by this ingenious Nobleman in vol. ix., of the *Edinburgh Journal of Science*; but as it is calculated only, or principally, for the larger specula, viz., those of two, three, or four feet diameter, it is not likely to be called for by the generality of experimenters on this subject: we therefore will merely refer such readers as are desirous of understanding its operation to the Work quoted above, and shall devote the remainder of this article to a machine on a smaller scale, lately presented to the Society of Arts by Dr. Green, of Cork, which is applicable to specula of a medium size, but is, perhaps, rather more complicated than is necessary.

This machine is represented in plate lxxxiv. fig. 3, 4, &c. The length of the frame *a b* is 5 feet; the two long bars *c, d* are $2\frac{1}{2}$ inches broad by $3\frac{1}{2}$ inches deep, and are 9 inches asunder on the outside; the machine stands upon four legs, $2\frac{1}{2}$ inches square, which raise the upper face of the bars 15 inches high. The cross piece *a*, through which the mandril *e* passes, is 2 feet 8 inches long, $4\frac{1}{2}$ inches wide, and $2\frac{1}{2}$ deep; the cross bar *b*, at the other end, is 20 inches long, $3\frac{1}{2}$ wide, and $2\frac{1}{2}$ deep. The square front *f f*, which carries the pillar *g*, is 12 inches square and $1\frac{1}{2}$ thick, and is firmly fixed by seven screws to the upper surface of the cross piece *a* and of one of the long bars, as is plainly seen in the figure. This board covers one part of the bar and part of the cross piece *a* to their edges; it stands $1\frac{1}{2}$ inch above the edge of the frame, and firmly binds the long bar *d* to the cross piece *a*. The legs are firmly mortised into cross pieces at the bottom, $2\frac{1}{2}$ inches wide and $1\frac{1}{2}$ thick. The mandril is 14 inches long, $1\frac{1}{2}$ diameter at its shoulder, tapering gradually to two-fourths of an inch at the lower end, in which there is a small hole drilled to rest upon a pointed screw of hard steel *h*, which is attached to the lower cross piece. The upper part of the mandril works in a bell-metal collar, let into the upper cross piece *a*, and on a level with its upper surface: the mandril is to be ground into this collar until its shoulder shall stand only one-quarter of an inch above the surface of the frame: the mandril must stand truly perpendicular, and at the distance of about 1 inch from the leg of the machine. The screw of the mandril may be about three-fourths of an inch in diameter, and as much in length. The bell crank *i* has each arm 9 inches from the centre of motion to the joints of the connecting rods *j*; it works upon a steel arbor, which passes through the pillar *g*, which is to be firmly fixed near one corner of the square board *f*.

Pl. lxxxiv.
Fig. 3, 4, &c.

Manufac-
tures.

This pillar is $2\frac{1}{2}$ inches high; the crank is secured by a nut, and is to be ground on the arbor so as to have a very smooth and steady motion. The double joints of the connecting rods *j* and *k* are each formed of one piece of metal as represented, one cut receiving the ends of the arm of the bell crank *i*, while the other cut receives a steel plate *l*, which is riveted into the end of the connecting rod *k*; this forms a steady universal joint when steel pins are put into the holes. The fly wheel *m* is 26 inches diameter, and weighs from forty to fifty pounds. The screw upon the end of the mandril is destined to receive a disc or chuck of cast iron, 7 inches diameter, 1 inch in thickness at the centre, and gradually decreasing to half an inch at the edge, having its upper surface quite flat. Upon the flat surface of this chuck the pewter polishing tool is fixed with six common $1\frac{1}{4}$ inch screws which pass through the chuck, in which there are six holes near the margin, and screw into the pewter. The margin of the pewter polisher is elliptical, 10 inches by 9, and $1\frac{1}{2}$ thick. Between the chuck and the polisher a circular disc of sheet lead *n*, 15 inches diameter, is to be interposed; its edge is to be turned up into the form *n*, exactly resembling a common fryingpan, about 1 inch deep, and 12 to 13 inches diameter; it is to retain the mud that is formed in grinding or polishing, and it thus keeps every thing clean. To the under surface of the chuck a brass ring, 7 inches diameter outside, $5\frac{1}{2}$ inside, and three-eighths thick, is to be fastened to six screws; and when on the chuck, and the chuck on the mandril, its edge is to be turned with a groove like a pulley, in which a screw of about ten threads to the inch is to be cut. The face of the pewter polisher is also to be turned to the degree of convexity required after it is affixed to the chuck. An endless screw *o* runs in this pulley, and gives a slow rotation to the chuck and its polisher. This screw is of steel hardened and tempered, and by notching three or four threads at its end like a tap it will cut the pulley in its place; when it is cut, by moving the bearing in which the other end of the screw runs about an inch nearer, the pulley will cause it to revolve. The screw receives its motion from a pulley *p*, 4 inches diameter, fixed upon its axis or shank, and a band which also passes over the small pulley *q*, of 2 inches diameter, upon the axis of the fly. The fly is moved by the pulley *r*, 4 inches diameter, which corresponds with the wheel *s*, 12 inches diameter, on the axis of which is the winch handle *t*, which gives motion to the machine. This same axis has a second pulley *v*, 12 inches diameter, and upon its axis are two other pulleys, *w* $9\frac{3}{4}$, and *x* $7\frac{1}{2}$ inches diameter. The axis of these three pulleys is raised 4 inches above the level of the frame by two solid blocks; one, *y*, only is seen. One of the legs *z* of the frame is longer than the others, and projects six inches above its upper surface. A groove is to be cut in its top to allow another axis *I* to rest in it 5 inches above the frame; this axis is supported horizontally by a pillar 2, in the model; but it would be more simple to make the other leg as long as the leg *z*. On this axis are two pulleys, 3, 9 inches diameter opposite to *w* and 4, $11\frac{1}{4}$ diameter opposite to *x*, so that the same band can be passed from one pair of pulleys to the other pair in an instant, without making any alteration in its length.

The pulleys are all formed of three pieces, to prevent warping, viz. a three-quarter-inch plank in the middle, having a three-eighth plank glued on each side of it with

the grain of the two latter at right angles to that of the former. When dry, let them be wedged with glue upon that part of their axes where they are to remain, and let them be turned on their axes with their edges a little convex, which form has the property of preventing the band from slipping off. A strip of woollen cloth glued on the edge of the pulleys will increase the adhesion and allow them to work with looser bands. The axes are formed of three-quarter-inch square bars of scrap iron, and require no forging; the bands may be made of buff strap, or of such leather as the saddlers employ for stirrup leathers, and should be fully an inch broad and put on pretty tight. The pulleys 1 and 2 need not be more than an inch in thickness, and their band of one-half inch broad may be left very loose. The pivots of all the axes run in boxes or bearings of box-wood, and are screwed up pretty tight. These are easily made; they give a very smooth motion, little disposed to heat, wear, or dirty the oil, and are far preferable to brass or bell metal.

Upon the projecting extremity of the axis *I*, which carries the pulleys 3, 4, is fixed a strong straight crank 5, shown larger in fig. 4, about six inches long, and graduated on its face to tenths of an inch. On its slide is an iron box or square tube 6, having the outer side 6 projecting so much beyond the other three sides towards the centre of motion that a steel stud 7 affixed to it can be made to slide over the centre of the axis *I*, or be placed at any required distance from it, and be kept in its place by the pressure of the screw 8, which passes through one side of the box and bears upon the crank 5, thus rendering the length of the crank variable at pleasure, and capable of being altered in a few seconds. On the base of this stud 7 is a fast pulley 9, an inch in diameter, and having a deep groove in it; the rotation of this pulley gives motion to the mirror; on this stud hangs the connecting rod 10, 10, fig. 3, which is attached to the back of the mirror. A nearly similar crank 11 is upon the end of the axis which carries the pulleys *v*, *w*, and *x*, but at the opposite side of the machine. The only difference between them is that the sliding box of the crank has no pulley upon its steel stud, which receives the connecting rod *h*, giving motion to the bell crank *i*. The connecting rods are attached to the cranks in the following manner: a hard steel plate of the form 12, fig. 5, is firmly screwed or riveted to the side of the wooden connecting rod 10, next to the crank. The notch of this plate hooks upon the neck of the stud 7, and they should fit each other accurately. The plate 13, which revolves round a screw on the under side of the connecting rod, being pushed under the stud, keeps the plate 12 in its place, and prevents it from unhooking. This is a convenient mode of fastening the rod 10, 10, in particular as it frequently requires to be detached very quickly in the act of polishing.

(1111.) *Motion of the speculum.*—Let a back (as it is called) be prepared of hard pewter, two-thirds the diameter of the speculum, and for a 9-inch mirror fully half an inch in thickness at the centre, and decreasing gradually to one-eighth of an inch at the edge. Let its under surface be turned as nearly as can be to fit the back surface of the mirror. A female screw, $1\frac{1}{2}$ inch diameter, is to be turned in its centre quite through; this back is afterwards to be cemented upon the mirror with soft pitch, and its centre should accurately coincide with the centre of the mirror; a brass handle is to fit into the screw of this pewter back. It is of the form

Mechanical
Processes.

Method of
giving mo-
tion to the
speculum.

Manufac-
tures.

represented in fig. 7: the screw 14, half an inch long and $1\frac{1}{2}$ diameter; the flanch 15, $2\frac{1}{2}$ diameter and one-eighth in thickness; the cylinder 16, $1\frac{1}{2}$ inch diameter and one half long; a square prism 17, the largest that can be formed out of the cylinder, and an inch in height. On the top of it stands a screw 18, half an inch in diameter, and an inch in length. This handle is to be screwed tight into the pewter back before it is struck on the mirror, and a circular disc of thin paper should be pasted on the end of the screw, so as to cover the joint, to prevent the pitch from entering it, which would render the removal of the brass handle a matter of difficulty. The cylinder 16 of the handle receives the rings of two connecting rods 10, 10, and j , and their form is easily understood by referring to fig. 8; a ring of stout sheet brass, 2 inches in width, and nicely fitting upon the cylindrical part of the handle, is represented by 19. A hinge 20, to allow the ring to follow the curvature of the polisher, terminates in two plates of brass 21, 21, which are firmly riveted to the wooden connecting rod 10, 10. The length of the connecting rods must be such that, when the studs of the sliding boxes of the two cranks are placed over the centres of their respective axes, the sides or arms of the bell crank shall be parallel to the sides of the square board on which it stands; and the centres of the two rings of 10, 10, and j , shall both coincide with the centre of the polisher when they are put upon the cylinder of the brass handle, which is screwed into the pewter back attached to the speculum. A washer of fine card should be interposed between the flanches of the handle and the ring next to it, another between the two rings, and a third between the upper ring and the wooden pulley 22, which keeps the rings in their places and gives rotation to the mirror. This pulley should be made of light wood 14 or 15 inches diameter, and three-eighths in thickness at the edge, in which a deep groove is to be cut, but strengthened at the centre by a piece of hard wood, making its centre there fully an inch, gradually tapering off so as to support another 6 inches of its centre. This pulley fits upon the prism of the brass handle, and is fastened down by a circular nut of box-wood, which screws upon the upper or smaller screw of the handle. It is seen in its place in fig. 3, and receives rotation from the first pulley 9, attached to the stud 7 of the variable crank 5, by a gut band 23, 23; 24 is a small guide and tightening pulley, 2 inches diameter, on one end of a flat strip of brass about 6 inches long, the other end of which is fastened by a screw to the upper part of the connecting rod 10, 10. This bar moves stiffly round the screw, and will remain at any angle to which it is set.

Action of
the ma-
chine.

(1112.) *Action of the machine.*—The action of the machine can now be easily understood. If either of the cranks be shortened to nothing by fixing the stud in the centre of motion, the other crank will cause the mirror to move backwards and forwards with cross strokes over the centre of the polisher; while the polisher revolving slowly in one direction, and the mirror in an opposite one, the different parts of each will have their relative positions perpetually changing. The extent of the stroke given by each crank will be double the length of the crank; and this is altered in an instant by sliding the box with the stud upon the crank.

Let us now suppose both sliding cranks set to the same length, and the band passing over the pulleys w and 3, of $9\frac{3}{4}$ and 9 inches diameter, and suppose their

cranks, at any moment of time, to be vertical, and of course at right angles to their connecting rods; now as their motion is so nearly equal, they will remain nearly parallel to each other for one revolution, and their joint action will be to cause the mirror to move in the diagonal of the two forces, and it will describe two cross strokes in nearly a straight line over the centre of the polisher. When, however, the pulley w shall have described three revolutions, the cranks, which were at first parallel, will now be found at right angles to each other. The effect now produced will be, that one crank, at right angles to its connecting rod, will propel it with its greatest velocity, while the other crank, parallel to its connecting rod, gives it scarcely any motion; and the mirror being at this time at its greatest distance from the centre of the polisher, the first crank, acting upon it at right angles as a continually deflecting force, will cause it to describe a curve nearly circular around the centre of the polisher; at every revolution this curve approaches the straight line or transverse stroke over the centre of the polisher, and at the end of three more revolutions of the pulley w it will again give a stroke nearly transverse, which will again gradually change into a curve in the opposite direction. If the band be now passed over the pulleys x and 4, of $7\frac{1}{2}$ and $11\frac{1}{4}$ inches diameter, the changes from curves to a position of a straight stroke succeed each other so rapidly that the path of the mirror will in some degree resemble a capital L in writing, which being frequently repeated will cover the polisher in every direction.

In the above instances we have supposed the two cranks of equal length; but it is obvious that, by varying their proportion to each other, an endless variety of curves can be produced. Were it desirable to polish by circular or elliptical strokes round the centre of the polisher, it could easily be effected by having two more pulleys in the arbors moving the cranks, each being $9\frac{3}{8}$ inches diameter. As the two cranks would now move with equal velocity, by setting them at right angles at starting they would retain their relative position; but if their length were equal, the centre of the mirror would move in a circle around the centre of the polisher; but if the length of the cranks were unequal, its path would be an ellipse.

(1113.) *Path described by the mirror.*—For the use of those who have not had an opportunity of seeing the machine or model in action, Dr. Green has traced a few diagrams, describing the path of the centre of the mirror over the surface of the polisher: "This was effected by fixing a piece of card pasteboard in the place of the polisher, and uniting the two connecting rods upon a piece of tube, which allowed a pencil to pass through it freely yet steadily, and the pencil was loaded with a weight sufficient to cause it to trace. In forming fig. 8 both cranks were fixed parallel to each other, and vertical, which placed the pencil in the centre: one quarter of a revolution of the cranks carried the pencil to 25, which is nearly a straight line. At 25 it turns sharp, and traces the line to 26 somewhat curved, it then returns through another curve, and back again through a line still more curved than any of the preceding, and thus a path may be traced by the lines in the figure. When arrived at the fifth and sixth line, it will be seen that the curves are nearly circular, as the cranks are at this time at right angles to each other; the curves now begin to close in a direction at right angles to the first line, and by the eleventh or twelfth turn of the crank

Mechanical
Processes.

Path of the
mirror.

Manufac-
tures.

become very elliptical, and at last nearly straight; the cranks having again become parallel, the machine was stopped when the pencil came to the centre. The ratio of the diameter of the pulleys moving the cranks was about that of 23 to 24, and the cranks were of equal length: this Dr. Green calls the primitive figure of that ratio.

"Were the machine continued in action for as many more revolutions, a similar figure would be repeated; but not exactly in the same place, except the cranks became parallel precisely at the time of their being horizontal, which is very unlikely to happen.

"As both arms of the bell-crank are equal, the distance 26—27 will be twice the length of one crank, and the distance of 26—28 will be twice the length of the other crank, and those strokes which are nearly circular will have a diameter equal to those lines; but the very elliptical or transverse strokes will be to twice the length of the cranks, as $\frac{3}{2} : 1$, or as the diagonal of a square to one of its sides. This must never be lost sight of in calculating the length of stroke which one may wish to give to the mirror in polishing, as it is well known the length of stroke always commands the figure.

"Similar reasoning is applicable if the cranks be unequal, when one crank is double the length of the other. The lines will be similar to fig. 8, but included in a parallelogram whose sides are as 1 to 2. In this diagram the ratio of the pulleys is also as 23 to 24. These two diagrams were traced with a five-feet machine.

"Those who are practically acquainted with the effects produced upon the figure of mirrors by a difference in the method of working will readily perceive that any of the conic sections which have hitherto been produced by hand-polishing can with this machine be effected with far more certainty and regularity, as it is not possible for the most experienced workman to calculate the length of stroke he employs in polishing by hand. Nor is this all: heat, partially applied, has a surprising influence upon the figure of a mirror; and it is quite impossible to allow for the effect of that which is communicated by the hand when it is directly applied to the mirror, and the unequal pressure of the hand, (which no care can prevent,) I believe, often causes the vertex of the parabola to be found in some part of the mirror different from its centre."

The author gives the following practical hints for the guidance of those who may feel disposed to try polishing with the machine.

Practical
directions.

"In the first place the temper of the pitch is of primary importance, and it should be such that the cross furrows made in it should, at the end of four or five hours' polishing, be diminished in their breadth by about one-third part, and not more, or the pitch will, if so soft, never figure a mirror capable of giving a sharply defined image, although its general figure may appear parabolic, and its polish most exquisite. Secondly, I would advise keeping the polisher always moist, never allowing it to get nearly dry, as is the usual practice with workmen, to obtain a fine polish. This is done to prevent the extreme trouble attending the preparation of a powder of the necessary fineness for wet polishing. To procure such a powder, after long-continued trituration of colcothar or red oxide of iron in a mortar of porcelain or agate, I float off the finer parts with water in the usual manner, returning the coarser into the mortar; I then mix all the fine powder thus washed over in a tall cylindrical jar of thin gum-water; this

will keep the very fine particles suspended for a long time, and allow the heavier to fall to the bottom. The upper portion of the gum-water is then, at a proper time, to be carefully decanted off into another vessel; and, on being further diluted with water, it will, after two or three days, deposit a powder so fine that it may be applied at the last moment, if necessary. Having coated the polisher pretty freely with colcothar washed over with water in the usual manner, I work the mirror an hour and a half or two hours; I then wash it and the mirror well with a flat camel-hair brush and water of the exact temperature of the polisher. I then apply the very fine powder I have described, and wet occasionally with a solution of carbonate of soda, in the proportion of five or six grains to the ounce of water; this removes the harshness of the surface of the pitch without injuring its figure, as an increase of temperature always does. Thirdly, to insure a regular fine figure, it is necessary to alter the length of the cranks whilst the mirror is being polished; this I consider the most important and most essential part of the process. The mirror should be polished partly by very free and bold strokes, partly by very short, and partly by those of an intermediate length. To ascertain how frequently and to what extent these changes should take place is a very complicated subject, of most difficult investigation, and one on which I can at present speak with little confidence; but the relative length of the two cranks I would advise to be always kept between three to two and two to one. Fourthly, the polisher should always be surrounded with a sufficient quantity of water in the leaden pan to cover the bulb of a small thermometer; as pitch is so much affected by a small variation of temperature, that, should any considerable change occur during the process, it is in vain to look for any good result. Fifthly, great attention should be paid to the velocity of the mirror; forty or fifty strokes a minute, if the strokes be long in proportion to the diameter of the mirror, or from fifty to sixty if they are short, is as rapid a motion as ought to be employed; if quicker, it will heat the surface of the pitch and distort the figure of the mirror almost as much as the heat of the hand in hand-polishing, although the error produced will be in the opposite direction.

"Since writing the above description, I have been engaged in assisting my friend Captain H. Kater to get constructed a polishing machine of five feet in length. This gentleman, well known in the philosophical world as a zealous labourer in many departments of Science, the inventor and improver of numerous instruments, has devoted considerable attention to polishing mirrors, and particularly through the medium of machinery. On attentively examining the path of the mirror over the surface of the polisher, which it traverses in every possible direction, it occurred to him that it may not, perhaps, be necessary that the polisher should continually revolve. I fully coincided in his view of the subject, and subsequent experiments have confirmed the correctness of his opinion. This suggestion very considerably simplifies the construction of the machine, and I believe without any injurious effects upon its action. The rotation of the polisher is produced by several parts of the machine, which are by far the most troublesome to execute in its entire construction, and that motion not being necessary, disencumbers it of the following parts: the mandril and its collar; its large iron chuck which carries the polisher; the large brass ring having

Mechanical
Processes.

Proposed
simplifica-
tion of the
machine.

**Manufac-
tures.** a screw cut at its edge, the endless screw *o* with its pulley, the pulley *q* on the axis of the fly-wheel, and their band.

"In place of this apparatus we simply fixed a piece of inch plank one foot square firmly to the frame by four screws, with its centre in that part of the upper cross bar through which it was intended the mandril should pass in case we found it necessary to employ one. Another square piece of plank of the same dimensions was fixed upon the first plank, by one strong screw passing through both their centres, in such a manner that the upper plank can be turned at pleasure by the hand around this screw as an axis, and it moves so stiffly that it will remain in any position in which it is placed, without danger of turning by the action of the mirror. To this upper plank, the polisher and its leaden tray are fixed by four common screws. As the mirror is being polished, this plank is occasionally, that is, every fifteen or twenty minutes, turned round one quarter of a revolution; or the upper board may be turned round, by contact with the tangent screw, as in fig. 3, to keep it moving, its motion being so very slow. A mandril, though perhaps best, is not absolutely required to render that motion smoother.

"The next point for consideration is the mode of attaching the apparatus to the mirror; and this, I may observe, is of the greatest importance towards obtaining a satisfactory result with certainty.

"That many a fine mirror has been destroyed by separating the back is a fact well known to every person who has ever embarked in the delicate and often vexatious operation of figuring specula. If a mirror be bound, pressed, or restrained in any way, by even a very small external force while in the act of being polished, whatever figure it may in that state acquire will be changed to some other curve the moment it is released from that force. So delicately sensible are mirrors, that the slight blow required to detach the back if cold, or the annealing process they must undergo to melt the pitch, if heat be employed, I suspect may suffice to injure an exquisitely fine figure. For this reason I always leave attached to a fine Newtonian mirror the back with which it was polished. To remove this source of error and uncertainty, Captain Kater attached the apparatus to a loose back of strong tin, having a ring round it exactly like the cover of a common round tin canister, the ring being rather less deep than the thickness of the mirror, so as not to touch the pitch. The ring should be so much larger than the mirror that, when lined inside with soft leather, it may not press upon the edge of the mirror in any direction. This method rotates the mirror perfectly well, and the ring will not rise up in polishing if the edge of the mirror be perpendicular to its face. If the mirror be much bevelled at the edge, the apparatus must be cemented to it with pitch; but in this case I would advise a disc of soft and thick buck-skin leather to be interposed between them, taking care that the heat employed to cement them be so moderate as only to soften, not to melt the pitch, so that it may not enter the substance of the leather to harden it, but allow a slight motion between the mirror and the back.

"I am perfectly convinced that a loose cover such as I have described, having the pulleys 9 and 22, and cord-band 23, as in fig. 3, affixed to it, would rotate the mirror as well as the method I have hitherto employed, provided the edge of the mirror be without bevel; and

if in any case a back is to be cemented to a mirror, I would always advise a piece of soft leather to be interposed to prevent any strain between it and the pewter back."—*Trans. Soc. Arts*, vol. 1.

**Mechanical
Processes.**

Manufacture of Biscuits.

(1114.) The great extent of the British Royal Navy, and the still more extraordinary number of merchant vessels daily leaving the different ports of the United Kingdom, necessarily call for a great supply of ship bread or biscuit, the manufacture of which forms a distinct branch of the baking Art, and is in its process exceedingly interesting. While the steam-engine and machinery have been introduced in almost every other Art, that of biscuit-making has, till very lately, been performed by hand. So recently as the year 1833, the first application of these means has been had recourse to for this purpose. The machine is the invention of Mr. Grant, one of the civil officers in his Majesty's Victualling Office at Portsmouth, and is described below; at present our object is to explain the manual process, which, is extremely curious. This process is of course somewhat, but very little, different in its minutiae in different offices; we shall confine our description to that followed in his Majesty's Victualling Office, Deptford. The corn is received from the markets, and is cleaned, ground, and dressed at the splendid corn-mill of that establishment, nearly resembling that already described under the article Flour-mill. The flour used in the manufacture of biscuits for the Royal Navy consists of a mixture of flour and middlings, or it is the flour which remains after the pollard and bran only have been extracted, the corn being highly dried before it is ground. The baking establishment consists of two long buildings, each divided into two baking offices, with six ovens in each, which are ranged back to back along the whole length of the centre of the building; a stone staircase being placed in the middle of the length, by which you first ascend out of one office to the height of the ovens, and down on the other side into the other office, for the convenience of superintendence. The kneading troughs and kneading boards, or breaks, are arranged round the outside walls of the building, one opposite each separate oven. The ovens are all wrought iron, in shape resembling the segment of an ellipse with an area of one hundred and sixty square feet. The furnaces, which are on the sides of the oven, are also of iron, and are heated by a powerful Welsh coal, which gives out a strong flame, and is conducted all round the oven. The number of men required to work each oven is five; these form a gang, and are denominated the *funner*, *funner's mate*, the *driver*, *breaker*, and *idleman*.

**Biscuit-
baking.**

**Biscuit-
baking by
the usual
process.**

Process.—The first operation is that of kneading, in which there is nothing remarkable. The proper quantity of flour is put into a trough, furnished with a cock for a supply of water, and here it is kneaded by the driver with his naked arms till it assumes the rough form of dough. In this state it is removed from the trough and deposited on a strong wooden platform or table, called a *break*, to be operated upon by the breaksman, who, seizes a strong lever called a *break-staff*, with which he presses down the dough, sits with his weight upon it, and, with a rapid jumping and most uncouth motion, carries the lever over the whole surface. It is then transferred to the moulding board, a strong table near

Manufac-
tures.

the mouth of the oven. Here it is cut into slips, and divided into lumps of the proper size for a biscuit. It is then moulded by the hands into its circular shape, laid in pairs one on the other, and subsequently docked, that is pierced with holes by an instrument called a docker; this stamp contains also the number of the oven, D for Deptford, and the usual King's mark. This number and the initial of the yard are specified, in order that, if any defect should be observed in the bread, it may be known where the fault rests. The biscuits, being stamped, are thrown six or eight at a time upon another table nearer to the oven's mouth, where are placed the other three men, one called the *turner*, another the *turner's mate*, and the third the *idleman*, who separates the double biscuit, hands them singly to the turner's mate, who, with great dexterity, and even with elegance, pitches them into the oven upon the peel, handled with equal dexterity by the turner, who places the biscuits as he receives them side by side throughout the whole area of the oven, drawing back his peel a short distance each time to receive the next biscuit. The speed and facility with which this process is carried on are very striking to the eye of a stranger. It of course varies a little, but frequently more than one hundred biscuits are thus pitched in and properly placed in a minute. It may be observed that, with the greatest dexterity, those biscuits first placed in the oven must be most baked; and to equalize this unequal effect the first are made larger than the others, so that the heat may be proportionally distributed; the oven, being filled, is closed for about ten minutes, when it is again opened and the biscuits withdrawn. During the time the oven is closed, and while the bread is being withdrawn, the process of kneading is going forward by the men not employed at the oven, to be ready to commence again as soon as it is empty.

The quantity baked each time, which is called a *suit*, is about 112 pounds weight before being placed in the oven, and which comes out 100 pounds, about 9 per cent. of weight being lost in the process. The number in this weight of biscuit is about five hundred and eighty, that is one with another; there are about six biscuits to a pound. The cost of labour is about one shilling and sixpence per hundred-weight.

The usual number of suits which each oven bakes in a day is twelve, and on extra occasions they can bake sixteen or seventeen; but, even at the usual rate of twelve per day, the twelve ovens will bake 14,400 pounds of biscuit by weight, or about 85,000 by number. It is but justice to those who have the management of this establishment to say, that the order and cleanliness throughout are truly admirable. On a stranger entering the door opposite the middle stone steps or staircase, he is struck with the perfect order and dexterity of the six divisions of the men, each one attired in a clean checked shirt, white linen trowsers, apron, and cap, and all plying their several avocations with a steady rapidity, but without noise or the slightest appearance of hurry or confusion.

Biscuit-
baking by
machinery.

(1115.) *Biscuit-baking by machinery.*—The hand process, such as is above described, had been almost the only means adopted till the year 1833, when a highly ingenious piece of machinery was invented for the purpose by Mr. Grant; and the importance of it will be at once seen when it is stated that, notwithstanding the Government bake-houses at Deptford, Portsmouth, and Plymouth were kept continually at work during the late

war, often with double gangs of workmen, the supply was yet so vastly short of the demand that it was necessary to have recourse to contractors to furnish the additional quantity required; and the wants of the shipping were sometimes so urgent, that bread brought to the Victualling Department in waggons was received in the street and sent off from the spot immediately.

The general superiority of machinery, when applied to a suitable object, over every other species of labour, is peculiarly evident as regards biscuit machinery. The processes on which the goodness of the bread mainly depends, are the thorough kneading of the dough, and its subsequent division into portions of equal size and thickness.

If the meal be not intimately and equally mixed with the water, some portions of the biscuit will be more wet than others, and will consequently require more baking than the dry parts; one of two results must inevitably follow, *i. e.* either the dry parts will become baked, perhaps burnt up, or the moist parts will remain unbaked and become what is usually termed "hard" or "flinty."

The same consequences must attend the division of the dough into biscuits of unequal thickness, or into biscuits of which every part is not equally thick. If the thin biscuits are not over-baked, the thicker must be under-baked, and the thin parts of a badly moulded biscuit will perish from the action of the fire, whilst its thick part is converted into "flint."

The prevalence of "flint" in ship biscuit is well known, though the cause of it has not been so generally understood: its origin, however, is sufficiently obvious, and is neither more nor less than that just pointed out.

The first process in the manufacture of biscuit by machinery is the mixture of the meal and water. The meal is conveyed into a cylinder 3 feet 3 inches in diameter, and the water from a cistern fitted at the back of the cylinder. Through the centre of the cylinder is fitted a rotary shaft, armed with knives, which work in a horizontal position. The spindle being set in motion by engine power, the knives pass through the meal and water: for the first thirty seconds very little amalgamation of the meal and water appears to take place, but after that period the dough commences to assume a consistency, and, in the short space of two minutes from the machine being set in motion, it will produce five hundred-weight of dough completely manufactured.

The cylinder is so fitted that the lower half is easily removed by means of a wheel and pinion from the upper sides, thereby forming a trough containing the new-made dough, from which it is with facility removed and placed under the breaking rollers, to undergo the second operation, that of kneading.

These rollers, two in number, weigh fifteen hundred-weight each, and are propelled by a two-throw crank shaft, by means of connecting rods and pendulum; they pass backwards and forwards over the dough during the space of three minutes, when the five hundred-weight of dough is brought into a solid, perfect, and equal consistency.

From the breaking rollers the dough is cut into pieces eighteen inches square, and placed on boards six feet by three wide, and which are made to pass under other rollers of equal dimensions, and by them rolled to the required thickness of a biscuit; the square of dough being by this operation pressed out so as to cover the surface of the board on which it is conveyed under the

Manufactures. cutting and stamping plate, which being constructed with mathematical precision, at the same moment cuts and stamps the biscuits complete for the oven, to which they are conveyed on carriages constructed for that purpose.

The machinery thus described requires only eight men and eight boys to supply the nine ovens in the Royal Clarence Victualling Yard, and they manufacture 12,000 biscuits, or one ton of bread per hour, at a cost of 4d. per hundred-weight.

From the quantity of bread that would be required for the Navy in time of war, the saving arising to the Country by the adoption of machinery for the manufacture of it would amount to £12,000 per annum, including a deduction of £10 per cent. on the cost of the machinery for wear and tear.

It is not an unimportant feature in the history of this machinery that furners (the individuals who have the charge of heating, as well as the management of the oven, &c.) are the only tradesmen who will in future be required for the manufacture of machinery biscuit, ordinary labourers and boys being competent to every other part of the work. This advantage can only be fully appreciated by those who had the means of knowing the difficulty experienced in procuring bakers, and the high wages demanded by them, during the late War. The machinery rescues the Government at once from the extortion of bakers hired to work in the public bakehouses, and from all the evils attendant on having recourse to contractors.

The machinery above referred to was first erected at Weovil, near Portsmouth, in 1832, under the direction of Sir John Rennie, and commenced working the following year. It has since been adopted with some modifications by Messrs. Fraser and Hullah, of Wapping, and will, most probably, soon come into more general use.

Mixing machine.
Pl. lxxxv.
Fig. 1, 2, 3. The first machine is the mixer, represented in fig. 1, 2, 3, plate lxxxv. Fig. 2 is an end elevation, fig. 1 a transverse section, and fig. 3 a longitudinal section. It consists of a cast-iron case *a, a*, nearly four feet long and three feet in diameter, enlarged, however, at the upper part, a few inches beyond the circular form, as shown by the upper dotted line in fig. 1. The radial lines in fig. 2 are merely ribs to strengthen the end of the case, opening upwards, to enable the workmen at any time to inspect the interior; and another larger flap or door, *c*, opens downwards, for the purpose of removing the contents of the case. This latter door is opened and shut by means of a quadrant rack *d*, worked by an endless screw *e*, which is moved by a pair of bevel pinions *f*, and these are acted upon by a small winch and axle attached to the supports *g g*. The operation of this machine is as follows: the requisite quantity of flour is sent down from the loft above by the shoot *h*, and the proper quantity of water is supplied from the small cistern *i*, fig. 3, which has a float and gauge, with a line and pulley to indicate the quantity admitted from a larger cistern above, and a pipe and cock to convey the water into the case. The flour and water being admitted, the central axle or shaft *k l* is put into gear with the steam-engine, by means of a coupling box *k*; the axis is thus made to revolve very rapidly, carrying around with it the frame of eighteen knives or mixers *m, m*. These knives, which are curved, as shown in fig. 1, are two inches wide and three-eighths of an inch thick at the back. They are connected at their extremities by similar longitudinal knives, which, in re-

volving, almost touch the lower part of the case. By these means it is evident that the flour and water must, in a short time, become thoroughly mixed. The paste is then removed by hand through the door *c*, and placed upon a table, which is as close as convenient to the mixer, and which is now to be described.

This table is shown in an elevation, fig. 4, plan, fig. 5, Fig. 4, 5, 6, and the transverse section fig. 6. It has a cast-iron frame and legs *a, a, a*, a cast-iron bed *b b*, six feet and a half long and three feet wide, in which are six holes *c, c*, &c., to receive friction rollers, on which run the boards to receive the dough. Fig. 7 is an enlarged section of the side *a* of the table, *b* is the bed, *c* one of the friction rollers, and *d* the board. The sides *a, a* of the table support a very heavy cast-iron roller *e*, eighteen inches in diameter, which, when resting on the table, is about two inches clear of the board *d*. This roller is made to run alternately, and with great rapidity, from one end of the table to the other, by means of a pair of beams ten or eleven feet long, attached to centres below the floor under the middle of the table, and made to alternate by a crank from the steam-engine; the upper end of one of these beams is seen at *f*, fig. 4, showing the groove in its extremity, to allow the axis of the roller to play in it as the beam alternates. It will now be evident that when a mass of dough or paste is taken from the mixer and placed upon the table, it must quickly be compressed by the roller into a cake equal in thickness to the distance of the roller from the board, which, in this case, is two inches. During this process a considerable quantity of dry flour is sprinkled on the dough and on the board, a large portion of which would be swept off by the roller and lost but for the troughs *g, g* at the ends of the board, which catch and retain it. Notwithstanding this sprinkling with dry flour, a small quantity of dough would occasionally adhere to the roller, were it not kept constantly and perfectly clean by means of two thin knives, extending on opposite sides along its whole length, and attached to two pair of curved arms, one pair of which, *h h*, is seen fixed to the beam *f*; when this operation is finished, the board with the dough is withdrawn, and another board introduced, on which the process is repeated. The first board and dough being withdrawn, is conveyed, on a series of friction rollers, to a second table, precisely similar to that just described, except that the roller approaches to the board within such a distance as is required for the thickness of the biscuit. The dough, which was reduced to a cake two inches thick at the first table, is cut into pieces and laid in portions on the second table, where it is quickly brought down to the proper thickness for biscuits; the board containing this comparatively thin sheet of dough is pushed forward, still running on friction rollers, towards a machine next to be described, while the workmen at the second table repeat their operations on the fresh portions of the dough which they have received from the first.

The machine towards which the board and sheet of dough now roll is shown in fig. 8; it consists of a strong cast-iron frame *a a a*, with cross beams *b*, supporting three or more pair of rollers *c c*, on to which the board is pushed. Immediately above is a thick plate of cast iron *d d*, three feet square, which is made to ascend and descend alternately by an eccentric, which acts on the rod *e*, the lever *f*, and guide rod *g*. The iron plate *d* is shown in the figure at its lowest position; it is, of course, at its highest when the dough and board

Mechanical Processes.

Fig. 9, 10.

are brought under it. When this is done, it descends and cuts the dough into hexagonal pieces or biscuits, by means of thin knives, one inch wide, affixed to its under surface, and arranged so as to form hexagonal spaces. A small part of the under side of the plate *dd* is shown on a larger scale in fig. 9, where, in addition to a portion of the hexagonal knives or cutters, will be seen a number of small dots or circles, which indicate the pins or prickers, to give the punctures to the biscuits before they are baked. These pins are as long as the depth of the hexagonal cutters, that is to say one inch; they are about one-third of an inch in diameter, and pointed at their extremities. The effect of all these cutters and pins would, however, cause the plate *d* to cling to and lift with it the sheet of dough. In order to prevent this, a very ingenious contrivance is introduced, a part of which will be observed in fig. 9. In each hexagon will be seen three arms branching from the centre; these are formed of iron, and each set is connected with a small vertical iron stem, which passes through the plate *d*, moving easily, and is surmounted by an iron ball two inches in diameter, acting as a weight to press the stem and the arms downwards. One of these balls, with its stem and arms, and a portion of the plate *dd*, is shown in fig. 10, where *a, a, a* are the three arms, *b* the stem, *c* the ball, *ff*, fig. 11, a portion of the dough, and *gg* a part of the board beneath. It will easily be understood that when the plate *dd* rises, the stem *b* will drop through its hole, pressed by the ball *c*, and, acting on the dough by the arms *a, a, a*, will disengage it from the hold of the prickers and cutters. When the plate *dd* descends to cut the dough, of course the arms *a, a, a* rise up to the plate, and the stem rises upwards in its hole, carrying with it a ball. There are as many of these balls and stems as there are biscuits, that is to say, about sixty in each square of three feet. These balls would therefore be seen on the upper side of the plate *d*, in fig. 8, but they are omitted for the sake of avoiding confusion. The hexagonal cutters do not so completely separate the sheets of dough as to prevent their being put whole into the oven, into which it is introduced by being laid on a plate of iron, which fits on the handle of the peel by a bayonet point. The sheet of dough, when baked, is broken into biscuits, which take the form marked out by the cutters.

The arrangement of the several machines would, in some measure, depend on the form of the building and other circumstances. They should be as near together as is convenient, in order that the boards may pass from one to the other on rollers; the mixing machine should be near the supply of water and flour, and the cutting machine should of course be near the oven. A series of rollers should be fixed against the wall, for the purpose of returning the boards to the first table after they have been emptied. At Portsmouth, this series of rollers was kept constantly revolving by the steam-engine, so that when the empty boards were placed upon any part of the line, they travelled up the mixer without further attention.—*Trans. Soc. Arts*, vol. 1.

Malting.

Malting.
History of
the malt
uties.

(1116.) When we consider the immense extent to which malting is carried in this Country, and the great revenue which the Government derives from this source, it will be admitted that, however simple the process may appear in itself, the true theory of it is of very great

importance; and yet, by the various methods followed in different Counties, it would appear that very little is known on the subject. It may be said, in few words, that malting consists in steeping barley in water for a greater or less time; then placing it in heaps till it begins to germinate; and, finally, in stopping the germination, and drying it in kilns for use. Simple, however, as this may appear, the subject was considered of so much importance a few years back as to lead to a Parliamentary inquiry into the methods pursued by different maltsters, who were divided, we may say, into two parties, one of which advocated the practice of sprinkling the malt on the floor, while the other party opposed the practice as exceedingly detrimental to the article produced, and as leading to frauds on the revenue. This inquiry led the Commissioners of the Excise to request Mr. Carr—who had formerly been a Supervisor of Excise, a good deal connected with that branch of the revenue, and who had studied the subject with great assiduity—to draw up his views on the subject; and we think we cannot illustrate the theory of this important process better than by laying before the reader the very clear and scientific theory of malting which he has promulgated, and which is published amongst many other papers in the Parliamentary Report referred to above.

(1117.) *Theory of malting.*—The interior of a barley grain, Mr. Carr states, consists of two distinct parts, a minute germ, destined to elongate into the future plant, and a portion of farinaceous and mucilaginous matter, stored up expressly for its future conversion into saccharine, as the pabulum of the germ in the earliest state of its vegetative existence. Theory of
malting.

The germ itself consists of two very different parts, the plumula (acrospire, in malting) and the radicle or root; both are united at the same end of the grain; but, in germinating, the radicle very soon pierces the husk, and, separating into several fibres, elongates downwards, while the acrospire, but much more slowly, advances through the body of the grain, and, piercing the opposite end, soon shoots up into a green blade, leaving the husk of the corn empty, and perfectly exhausted of its former contents. The radicle is much more rapid in its formation and growth than the acrospire, because, as it is destined to prepare and transmit to the stem nearly all its pabula, it is necessary that it should be sufficiently matured to perform this office by the time the acrospire has consumed the store which provident nature had laid up for it in the grain. There is no difficulty in comprehending the first dawns of vegetative life in the germination of barley; the grain, placed under favourable circumstances of moisture and warmth, imbibes both, and swells much; the radicle, lying the nearest to the exterior, is the most susceptible of these; it swells most, and first, under its new combination of moisture, acquires an attraction for the oxygen of the atmosphere. The oxygen, as it becomes fixed, produces two powerful effects; it gives up that portion of latent heat which held it in a gaseous state, and, by its fixation, enters into a new combination with the farina of the grain, converting it into an oxide, or, in other words, into a saccharine. The stem part of the germ, previously swelled by the moisture, and now invigorated by the heat produced from the fixation of the oxygen, acquires an attraction for the newly-formed saccharine, assimilates it to itself, and in the chemical action of union which ensues vegetative life is developed. Such simply is the natural process of germination in every

Mechanical
Processes.

Manufac-
tures.

species of seed, though here restricted to barley; and it is important to remark, that the heat arising from the fixation of the oxygen is the same which first becomes sensible in the couch, and afterwards continues to show itself in different degrees amongst the corn on the working floors; and in the nice adjustment and due regulation of this heat consist the most important part of the manipulations of malting.

The formation of the saccharine in the grain is slow and progressive, as the acrospire requires it; and hence it may easily be conceived that, between the first formation and final consumption, there must be a period of time when the largest proportion abounds in the grain; and this is the proper time for throwing the corn upon the kiln. Mr. Reynoldson, in his evidence, states that the saccharine previously exists in the barley, and that the process of malting only develops a substance which was already present in the grain; but this, like several other of his philosophical assertions, is so contrary to the natural fact as obviously to refute itself. The chemical and natural characters of malt differ so essentially from those of barley as clearly to prove that there has been not a mere development of a thing present, but an entire change of the original substance into another.

Practice of
malting.

(1118.) *Practice of malting.*—Malting then is nothing more than the promotion of a healthy germination of the barley up to that period when the largest proportion of saccharine has been formed; nor can any thing be more obvious than that, in a variety of modes to accomplish this, one must be superior to all the rest, and that not locally, but every where, because nature is every where the same. In every natural process, the varying of the means will necessarily produce a difference in the end; and, in the two modes of malting, by watering on the floors, or omitting to do so, there is so material a difference, not merely in the use or disuse of the water, but in the time, management, and other circumstances, that the one cannot but be superior to the other in the quality of its respective commodity. A single instance cannot be produced of any natural process whatsoever wherein nature permits the employment of two different means to produce precisely the same end. The application of this to the question of malting will be sufficiently obvious by separately considering the different branches of the case.

The radi-
cle.

The radicle.—This is by much the most important organ in malting; without a root the grain will never germinate, and with too much, the substance of the corn will be exhausted, and the malt on that account will be light and unproductive. This has hitherto either not been sufficiently known or attended to; in this, as in every other natural process, nature herself affords the best explanation. On the richest and best lands the roots of barley are short and the plant large and strong; but on loose and poor soils the roots are long, and the stem small and weak. In the one case the root, having readily found what it was in search of, stops; but in the other, nature is compelled to expend much of the pabulum on the more ignoble part of her production. On the floor of a malt-house the grain is worse situated than on the loosest and poorest land, for it contains no soil at all; and, if permitted, the root there would run out to some inches in length, and almost wholly exhaust the substance of the corn. To prevent this is one of the principal objects in the manufacture of malt, and hence too a just criterion is afforded for estimating the merit of different methods of working; for that method

which will accomplish the full malting of the barley with the least possible root is so far unquestionably the best, because such malt will have expended the least portion of itself on an object entirely unproductive. Now there is, perhaps, no one circumstance wherein the Hertfordshire method of malting differs so distinctly from the watering system as in its short and comparatively small radicle. This may be very clearly collected from many parts of the evidence; for the watering party even seem to have made a merit of it, by endeavouring to show that their own steepings, from the larger quantity of root which they contained, approached and even ran into floor charges far beyond the Hertfordshire steepings; and they thence endeavoured to infer that a larger opening was left in the latter for fraud, by the introduction and mixing of corn privately steeped. It is indeed certainly true that the Hertfordshire mode of working gives the floor gauges low, and the other high; but with this the question of fraud has very little to do, for mixing is seldom, if ever, practised in the whole floors; but the short and small radicle of the one, and long bushy root of the other, are decisive characteristics which are admitted by themselves, and which would, in the author's opinion, stamp a decided superiority on the Hertfordshire malt.

Mechanical
Processes.

That the radicle is actually formed from the body of the barley is too obvious to require any proof, and indeed it is universally admitted to be so; and, as it is afterwards burnt off on the kiln, and becomes mere waste, every particle of matter which it unnecessarily takes from the substance of the corn is just so much loss; and, though this has not been at all adverted to in the inquiry before the Committee, it does, in fact, constitute one of the most important portions of the subject; for it actually is the expenditure of the substance of the barley on the root, by working it too much out, which is the chief cause why malt manufactured under the forcing system of watering the floors is lighter and less productive than the malt made by the Hertfordshire mode without watering.

The acrospire.—In the malting trade a great diversity of opinion prevails as to how far the vegetation of the acrospire should be carried. This arises from a notion very general among maltsters, that just so far as the acrospire penetrates the grain it becomes malted, and that the impenetrated part remains unchanged barley. Mr. Carr says, "I trust, however, that I shall soon show there is nothing either of truth or nature in this notion. The evidence of Messrs. King and Clough sufficiently establishes that the best malt is made when the acrospire proceeds only two-thirds through the grain, and it is my present purpose to prove that their opinion and practice are supported by the natural reason of the case. I have already stated that it is the radicle which first acquires an attraction for the oxygen of the atmosphere, communicating it progressively to the interior substance of the barley, and forming, by its fixation and union with the farina, the first saccharine; and that afterwards the plumula, or infant stem, requires an attraction for the newly-formed saccharine, and by its chemical action is pushed into vegetable life.

The acro-
spire.

"In this statement a solution is given of the question of the acrospire; and the truth really is that the radicle is the only natural organ which malts the barley, or, in other words, oxidates the interior substance, and forms the whole of the saccharine, while the acrospire is simply employed in feeding upon it, and from thence

Manufac-
tures.

acquiring its growth and bulk. This obvious, and I trust just and natural, distinction in the office which nature assigns to each of those different members of the plant, sufficiently explains why the barley may be, and actually is, perfectly malted by the Hertfordshire method, though the acrospire has proceeded only two-thirds through the grain; because, in the more slow and natural growth of the acrospire, the root has had time to malt the interior substance beyond it, and even to the extreme end of the corn, whereas, in the more unnatural forcing of the watering mode, the acrospire is driven forward as rapidly, though without having any immediate connection with the oxidation; and thus an accidental occurrence has been erroneously mounted up into a cause. It is material to remark that, in brewing, the acrospire is insoluble and always appears so among the spent grains; hence the larger it grows, the more it contributes to waste. The preceding account of the radicle and acrospire so far simplifies the question of malting as to concentrate it to this limited rule; viz. that mode of working will necessarily be the best which can accomplish the full malting of the barley, with the smallest radicle and acrospire; for both, as I have already shown, are supported from the interior substance, and just in proportion as they are advanced in bulk, that portion of the malt which yields the fermentative extract will be diminished. In page 40 of the printed evidence Mr. Delafield states that he has found malt made by sprinkling to yield from fifteen to twenty pounds weight in four bushels less than an equal quantity of malt which had been watered; and in page 43 Mr. Martineau states that sprinkled malt affords only sixty-four pounds of extract, when a like quantity of unwatered malt gave as high as eighty-four pounds. Other passages of the evidence also prove that watered malt is lighter, and, on that account, less productive than the Hertfordshire malt; but no explanation of the immediate cause of so material a difference is any where attempted; here, however, it is the opinion of the author that the true cause lies in the comparative smallness both of the root and acrospire in the Hertfordshire malt, whereby less of the substance of the grain is consumed, and that it is the long and bunchy root and large acrospire of watered malt that renders it so light and unproductive."

Tempera-
ture of the
floors.

(1119.) *The proper temperature of the floors in malt-
ing.*—There is no one circumstance in the manufacturing of good malt that merits so constant and careful an attention to the working floors as the temperature. There is a certain maximum of heat that is the best adapted to malting, and with which the vegetation will proceed in the safest and most natural order; either above or below this temperature is a disadvantage, but an excess and fluctuation of heat are highly injurious in a malt-house. In whatever way the floors are worked, the temperature will continue to rise in proportion to the time they lie undisturbed, and the only method of checking the rise is by turning them. Moisture is the remote cause of all heat in vegetable substances heaped together, and containing a farinaceous or starchy matter. This matter passes into a state of fermentation, attracts oxygen from the atmosphere, which, in its fixation, parts with the latent heat it was before combined with, and, this accumulating in the heap, will frequently rise to inflammation. The heat of a dunghill, moist hay-rick, wet barley, and all other similar heaps of wet vegetable matter, originate in one and the same natural cause. In floors of malt the heat is always in proportion to the

quantum of moisture and repose of the floor. The chief object in a well-regulated malt-house is not only to preserve the floors in one equable state of temperature from the cistern to the kiln, but more especially to preserve every part of the same floor in an equal warmth. A departure from this produces an unequal vegetation. In the Hertfordshire method of working, as there never is any increase of moisture after the corn leaves the cistern, an equal and steady temperature in both of the preceding cases can be preserved with much certainty; but, under the practice of watering the floors, it is not practicable to maintain the same equal degree of temperature, either in the progress of the floors to the kiln, or in the different parts of the same floor; and the consequence is that a forced, a fluctuating, and an unequal vegetation is induced in the same steeping, and the malt thereby becomes greatly injured. It is heat in the first instance that dissipates the water which the grain had imbibed in the cistern, and renders subsequent watering necessary. The floors cannot be heated without an expenditure of moisture, for the warmth sweats the water out of the corn, and, when the floor is turned, the moisture on the husk flies off by evaporation; hence though the water is at first the cause of the heat, the heat again renders more water indispensable. The floors in Hertfordshire are never watered, simply because they are never heated; and it is the cool state in which they are kept in the early stage of malting that preserves the original moisture, and induces that slow and natural vegetation so necessary to prevent the substance of the grain from being run out.

Mr. Reynoldson, in his evidence, states that the water imbibed in the cistern is employed in forming the root, and that the root afterwards is employed in supplying the grain; and hence he infers that fresh water is necessary on the floors. This description is tolerably just when applied to the watering practice, but by no means so in that of the Hertfordshire method. In the former the cistern water, as has already been stated, is nearly all expended in the first five or six days by the employment of heat to drive out a rapid vegetation of the root; but in the latter, seven or eight days are necessary to vegetate a less root. It is in this that the two practices differ most from each other. Mr. Reynoldson also states that the water received into the grain becomes decomposed, and after such decomposition exudes from the grain in a state unfit for vegetation; and hence he again infers the necessity of fresh water by sprinkling. This must be said, however, to be an unphilosophical assertion. In the chemical analysis of water only two products are obtained, viz. hydrogen and oxygen; and these, when separated, have never yet appeared in any other form than that of gases. The decomposed water of Mr. Reynoldson is nothing more than the pure water imbibed in the cistern, and injudiciously sweated out on the surface of the grain.

In order to preserve the floors at a uniform temperature, and to admit of the free dissipation of the moisture arising from the process, a malt-house is supplied with what is well known under the denomination of a cowl, which is a somewhat conical cap open on one side, and having a vane or arm on the open side, so fixed that, as the wind shifts, the cowl shall turn on its spindle, and always present the boarded or close side to the weather, which prevents a drifting rain from beating in: but in still weather the rain will find admittance, which if the floor is loaded with malt retards

Mechanical
Processes.

Substitute
for the cowl.

Manufac-
tures.

the drying, and produces in some measure the evils of watering on the floor spoken of above.

Another inconvenience of the common cowl is that it prevents a proper regulation of the fire, except by varying the supply of fuel, so that in making high-dried malt it is by no means uncommon for the grain on the kiln to take fire, to the imminent danger of the premises. This consideration has led to the invention of a cap for a malt-kiln by Mr. Perkin, for which he received a reward from the Society of Arts. See vol. xlv. of their *Transactions*.

Pl. lxxxvi.
Fig. 1, 2, 3.

This is represented in plate lxxxvi., fig. 1, 2, where *a a* is the turn-cap, and *b b* the neck, in section; *c c* is a square iron bar or spindle sliding through a square hole in the middle of the iron plate or bar *d*, and through another in the middle of the beam *e*. The cap *a a* turns upon the upper cylindrical portion of the bar, and the bar itself is supported and hangs entirely on the chain *f* attached to the pulley *g*, which is mounted on a carriage on the beam *e*. On the same axis is a larger pulley *h*, with a chain attached to it at *i*, from which hangs a weight *j*, sufficient to balance the weight of the sliding bar *c c* and turn-cap *a a*. By raising the weight *j* the cap is lowered and finally shut, and on lowering the cap is raised quite up, or held at any intermediate height: *d e*, fig. 2, is a section of the neck between the bars, and fig. 3 a top view of the bar *d*, showing the hole through which the spindle passes; *k*, fig. 1, being a similar iron bar across the cap *a a*. The chain *f* should be attached quite close to the bar *c c* to lessen its tendency to lean on one side.

Effect on
the flavour.

(1120.) *Flavour of malt*.—A great deal is said by the party for watering on the subject of their being enabled to make their malt of a superior flavour by sprinkling; but the question of flavour, when applied to pale or common malt, resolves itself into this simple fact, that malt which is worked in the most pure, clean, and natural manner will be the most free from all adventitious and improper flavour. While pale malt is worked on the floors, all that can be done is not to give, but to guard it from any peculiar flavour. On the kiln the case is widely different; there, just in proportion as the fire is urged slowly or rapidly, less or more of flavour and colour will be given to the malt; it is in this way only that all malt expressly intended for the brewing of porter has its peculiar flavour and colour given to it; but the flavour of ale, generally speaking, is derived from a different source. This latter arises from the union of a peculiar oil of a greenish colour, naturally abounding in hops, with a portion of the unfermented wort, and the mucilage and alcohol of the fermented parts; these, judiciously blended together in a due proportion, give to ale its agreeable taste; but the palate being an arbitrary organ, and differing widely in different places, no established rule can be laid down for adjusting the flavouring of ale. In some places the sweet taste of malt is required to be pretty full in the mouth, by leaving a larger proportion of the unfermented wort; while in others it is required to be almost entirely dissipated by a more complete fermentation; and between these a variety of flavours may easily be imagined. What has been said will be sufficient to explain the case so far as regards that flavour which it is desirable to obtain; but there is another point of view in which it is to be considered, and that is, those bad flavours which malt acquires in its progress through a manufacturing state, and which greatly depreciate its value. The principal

of these, and indeed the only one with which the present inquiry is immediately connected, is that of mouldy malt, arising from the vegetation ceasing after having made some progress. Most of the grains which are bruised by being trodden under the feet of workmen or others while in a state of malting pass into a mouldy or putrid state; but the principal source of mouldy malt is in wet grain being buried under other corn, and too long excluded from the influence of the atmosphere. A simple experiment will sufficiently illustrate this: if a sample of half-malted barley be placed under a bell glass, air-tight at the bottom, the corn will vegetate freely until the enclosed oxygen is all consumed, when the vegetation will cease, and the grain will pass into a state of decay similar to mouldy malt, and the more moist the grain was when enclosed under the glass, the sooner it will become mouldy.

Mechanical
Processes.

In watering on the floors it is invariably the practice to turn over the grain immediately after it has been sprinkled; hence the wet corn is placed at the bottom; and it will necessarily happen that some of this will again be thrown undermost in the subsequent turnings, and this cannot fail to destroy the vegetation, and to render such grain mouldy; and not only the grains individually dead, but all others with which they happen to come in contact, will acquire a disgusting taint, which will afterwards materially affect the flavour of the liquor drawn from the malt.

(1121.) *Weight of malt*.—Several erroneous opinions are delivered in the evidence given before the Committee respecting the goodness of malt being determined by its weight. Abstractedly considered, weight indeed does not afford any certain data for estimating the worth of malt, because bad malt may be either heavier or lighter than that which is good. If the vegetation of the grain has been imperfect, or not carried sufficiently far, the product will be part malt and part barley, and of course heavier than good malt. But if, on the other hand, the vegetation has been carried too far, too much of the substance, and of course weight, of the grain will have been driven out, and the malt will be light in proportion as the injuring cause has been allowed to operate. In this way malt may be rendered light and unproductive to any extent at the discretion of the maltster. But, notwithstanding all this, in every instance where the grain has been perfectly malted, weight is the only certain standard now known for determining the value of malt; and this is now so well understood in the markets that it is not unusual for the buyer of malt to be provided with a pair of scales and a small measure, and to govern his opinion of the price by the weight which his measure of the sample yields. In all malt, therefore, which has been perfectly malted, there can be no question of the heaviest being the best; and in this respect the Hertfordshire malt preserves a distinguished superiority over all watered malt.

Weight of
malt.

(1122.) *Varieties of malt*.—Strictly speaking there are only three, viz. brown, amber, and pale malt. The first two are peculiar to porter, and have special reference to its flavour and colour; the third is the general basis as well of all porter as of every species of malt liquor, and it is the only one which merits any consideration in the general question of malting. Brown malt receives all its peculiar qualities in the kiln, by an operation called blowing. It is spread there very thin, and a very quick and active heat is passed through it from flaming faggots. The sudden application of the

Varieties.

Manufac-
tures.

heat converts the moisture in the grain into vapour, which blows up the husk, and the heat catching it in its distended state hardens and prevents it from collapsing; hence the grains of such malt are large and hollow, and increase the measure from one to two bushels in a quarter. The saccharine of this malt is nearly all destroyed by the operation of the fire, and its sole object in porter is to communicate flavour and colour; but as these qualities are probably to be obtained from other materials than malt, some porter brewers are not using it at all, and the making of it is very rapidly declining. Amber malt is a species between brown and pale, and is also made on the kiln by giving it less fire than the former and more than the latter. It is still generally used in porter along with pale malt, but the quantity made is inconsiderable.

Revenue.

(1123.) *Revenue derived from malt.*—The first malt tax was established in England during the reign of Charles I., but assumed a more particular character in the reign of William III., when, in 1697, a duty of 6d. per bushel was imposed. This was at first given for two years and a quarter, but was afterwards granted from year to year. The first permanent duty on malt was granted in 1760, at the rate of 3d. per bushel: a further addition to that was made in 1779 of 15 per cent.; and in the next year, 1780, another permanent addition was made of 6½d. ²/₁₀ per bushel. These several duties were consolidated in 1797 into one permanent tax of 9½d. per bushel, in addition to the old tax of 6d. per bushel; a further permanent addition was made in 1802 of 1s. 0½d. per bushel, and in the following year a war addition of 2s. per bushel; so that in the latter years of the War, and for some time after, the total malt duty amounted to 4s. 4d. per bushel. Gradual reductions have since been made, as will be seen by the following Table, which shows the amount of the malt duties for twelve years; viz. from 1820 to 1831, with further particulars therein stated.

TABLE, showing the Quantity of Malt made in England and the Revenue on the same, from 1820 to 1831.

Years.	Produce of duty on malt in each year, from 1820 to 1831, both inclusive.	Number of bushels charged with duty in each year, from 1820 to 1831, both inclusive.	Quantity imported into Great Britain from Ireland in each year, from 1824 to 1831, inclusive.	Quantity brought into the Port of London in each year, from 1820 to 1830, inclusive.
1820	5,088,195	27,889,210		195,878
1821	5,360,705	32,088,466		214,673
1822	3,918,001	28,282,292		221,108
1823	3,251,334	28,168,658		232,309
1824	3,999,419	32,573,990	1,173	233,638
1825	4,384,163	36,295,843	10,826	256,813
1826	3,955,935	32,468,778	1,202	275,787
1827	3,601,042	29,613,502	571	241,756
1828	4,623,113	36,794,520	853	229,934
1829	3,814,305	29,153,675	2,011	226,723
1830	3,436,271	35,160,809	2,820	218,261
1831	4,359,333	40,334,987	10,888	

(1124.) *Revenue on hops.*—Although the revenue on hops is not, in reference to our Work, necessarily

connected with that of malt, yet they are so collaterally combined that it will not be thought inconsistent to give the following historical sketch of the revenue arising from hops, derived from an authentic source, viz. The Report of the Commissioners of Excise Inquiry.

The first duty on hops was imposed by the 9th Anne, c. 12, at 1d. per pound. It was fixed at its present rate of 2d. per pound by the 45th Geo. III. c. 94.

The duty does not extend to Ireland, but hops imported from thence pay the English duty.

No drawback is allowed on hops exported to Ireland; but a drawback of the whole duty is allowed on hops exported to the Isle of Man and to foreign parts.

A return of the rates and amount of duty since 1770 is given at page 3 of the Report, showing the extraordinary fluctuations of the duty, varying from £14,913, the lowest amount in any one year, viz., in 1783, to £476,895, the highest amount, which was in 1826.

A return is also given of the number of acres under cultivation for hops in each year since 1807, which shows a gradual increase since 1832, the number of acres cultivated in the three following years having been,

In 1832 47,101 acres.
1833 49,187 „
1834 51,273 „

The number of persons surveyed in 1834 is stated to have been 7242, being the greatest number surveyed under any one of the growing-duty trades, except that of malt.

A full statement is given in the Report of the regulations for charging and collecting the duty on hops, which objects are carried on in a different manner from that of the other duties of Excise, being invariably completed in a period of one or two months, temporary assistant officers being employed for the purpose, which has been found more economical than employing a part of the permanent establishment of the Excise.

The total number of such officers has been in each of the last three years 270, and the total expense as follows, viz.

In 1832 £3316
1833 3432
1834 3675

forming a very small per-centage on the revenue derived from a good crop.

It appears, from letters addressed to the Commissioners by Members of Parliament representing the hop districts, that the growers are generally satisfied with the present arrangement for the collection of the duty, and are not desirous of any change, either in the rate of duty, or in the regulations under which it is charged.

The Commissioners call attention to the evidence of Mr. Ellis, of Barming, as entitled to particular weight, from his being the most extensive, as well as one of the most experienced cultivators of hops in the Kingdom, the number of acres cultivated by him being at present 500, the greatest number cultivated by any other person being 164 acres.

Sir Francis Doyle and Mr. Dehany consider the duty to be well and cheaply collected: but they suggest that the period allowed for claiming the drawback on hops exported, which is now indefinite, should be restricted to three years from the growth. The Commissioners of Inquiry recommend the adoption of this suggestion.

Mechanical
Processes.

Manufac-
tures.

Mr. Dehany also suggests the extension of the duty to Ireland, by which one of the few remaining distinctions which prevent the trade between the two Countries from being in all respects a coasting trade would be removed; and he considers there will be the less objection to it, as there are very few, if any, hop-growers in Ireland.

The Commissioners express their concurrence in Mr. Dehany's suggestion.

The question of the extent of credit which is allowed by law to the grower of hops, before his duty is collected, is fully entered into in the Report.

By the original Act of Anne a credit of six months was allowed, but under the 1st and 2d Wm. IV. c. 53, a full year must now elapse before the duties are entirely discharged: an extent of credit very much exceeding that which is allowed in any other case. It will be sufficient here to state, that the Commissioners of Inquiry refer to their Reports on paper and on malt, in which they have fully explained the opinion they entertain, "that Excise duties ought to be collected upon the articles charged, as soon as those articles shall be ready to be disposed of by the maker;" an opinion which they conceive to apply with greater force to the case of hops, in which a much more protracted period of payment is given, although the sale of hops generally takes place as soon as they are ready for consumption.

The Commissioners, however, express their sense of the difficulty of withdrawing an indulgence which is in part coeval with the imposition of the duty itself; but, being persuaded of the mischief which arises from the extension of credit in Excise duties, they recommend that the attention of the department of Excise should be called to the possibility of effecting an arrangement on terms satisfactory to the planters, under which this duty might, with respect to the time of payment, be assimilated to the other duties of Excise.

The Commissioners conclude their observations by a few comments on the effects which the high customs' duty of £8 11s. per hundred-weight on hops imported from foreign Countries has, in confining the supply in a great degree to the home grower, and thereby increasing the cost to the customer in England; a species of monopoly which would prevent the consumer deriving the benefit of a reduction of duty, by a corresponding reduction of price in the market; and, under these circumstances, they express their opinion, that there seems to be no reason why the revenue should not benefit by the present amount of duty, more especially as hops are comprised in that class of articles to which they have already referred in their Seventh Report, as being more fitting subjects for taxation than those which may be reckoned among useful manufactures.

Porter Brewing.

Porter
brewing.

(1125.) In our alphabetical division we have an Article descriptive of the process of brewing on a small scale for domestic purposes; we shall confine ourselves here, therefore, to a description only of the processes and machinery employed in the larger establishments, particularly in our metropolitan porter breweries.

Porter originally differed only from other kinds of beer of the same degree of strength by being brewed from brown or high-dried malt, which gave to it the peculiar colour and flavour which distinguish it from other beer, as described in Art. 1122; but at present it is brewed

from a mixture of pale and brown malt, the colour being less than formerly, or with all pale malt, and the colour given to it by certain colouring matter, such as burnt sugar, or burnt sugar of concentrated wort, &c. All London porter is professed to be what is called entire butt, that is, of one kind only; but it is more commonly compounded of two kinds, or rather the same liquor in two different stages, the due admixture of which is palatable, although neither is good alone: the one being new or mild, and the other staler or old; the former is that which has the slight bitter flavour, from having been lately brewed, the other gives the pleasant astringent character which distinguishes good porter. This mixture, however, is not made by the brewer when he supplies publicans with it for sale. In these cases the two different qualities are sent in different barrels, and the publican mixes them to the taste of his different customers, which was done formerly in the cellar; but this department of trade, like all others, has benefited by mechanical contrivance; and the matter is now so managed that pipes are communicated from different barrels in the cellar to a beer pump in the bar, and the beer is thus drawn and mixed with the greatest facility. The usual beer machine has four pumps, but only three spouts, because two of these pumps are connected with one spout. One of these two draw from the mild and the other from the stale barrel, and the tapster, by a dexterous management of the handles, works the two pumps so as to draw in any proportion from each; and to an indifferent observer, as all the liquor is delivered from one spout, no mixing would be suspected.

The London brewers, in consequence of the large scale of their business, have been led to study with the most minute attention every thing which can tend to improve their beer, or to economize the materials of which it is composed, as also to diminish the labour of removing such large quantities of liquor from one part of their extensive premises to another, and to substitute as far as possible mechanical power for that of horses and men.

The first porter brewer in London who erected a steam-engine for this purpose was the late Mr. Goodwynne, and it was the first engine erected in London by the late Mr. Watt. Another was soon after put up by the celebrated brewer Mr. Whitbread, at his establishment in Chiswell-street, where many other improvements were introduced. Indeed it is commonly asserted that the steam-engine was first erected on these premises, which is, however, a mistake. The writer of this article has been assured by Mr. Goodwynne that when Mr. Watt proposed to Mr. Whitbread to erect a steam-engine on his premises he decidedly refused, and that Watt subsequently applied to him, that he agreed to make the trial, and that this was the first steam-engine which Watt erected in London. Whitbread's was, however, for a long time the most scientifically arranged brewing establishment; but at present, we believe, this claim is due to the Golden-lane brewery.

The water employed by the porter brewers in London for the brewing part is mostly drawn from deep wells, although a very popular notion prevails that it is the Thames water which gives to London porter its peculiar quality. This is, however, erroneous. There is an immense quantity of water below the London clay which is in communication with springs considerably elevated; so that by sinking a well 150 or 200 feet deep, so as to penetrate and pass through the clay, an almost un-

engine in
breweries.

Source of
the water
for the
London
breweries.

Manufac-
tures.

bounded supply of the very finest water is obtained, and is generally employed by the London brewers: the other water supplied to these works by the different water companies being only for the purpose of cleansing &c. Referring again to the wells, the moment the clay is pierced the water rushes up so violently, in consequence of the height of the reservoirs in the chalk with which it is in communication, as to fill the whole of the well even to overflowing in a few minutes. With this pressure the sand between the clay and the chalk is forced into the well with the water, so as nearly to fill it up, and thus obstructs the free passage of the latter. This is remedied by driving down a copper pipe before the clay is quite pierced, and then boring out the part filled into the pipe. When the borer is removed the water again rushes in, bringing sand with it, but of course in less quantities, which, as the upper end of the pipe is many feet above the bottom of the well, affords room for lodging the sand without choking the well; and while the water is not drawn too rapidly, the supply is plentiful and uniform.

The source of water being thus secured, it has to be raised into the reservoirs, of sufficient height to supply the whole brewery by the steam-engine, which also works the machinery. From the reservoirs pipes are laid to convey the water to any vessels in the work where it may be required. The principal of these are the coppers, of which there are two, three, or more, according to circumstances. The water being heated in the coppers is conducted by a pipe to the mash-tuns. During the process of mashing, the malt is kept constantly stirring by machines in each tun, turned by means of bevel gear connected with the steam-engine.

Crushing
rollers for
preparing
the malt.

(1126.) The malt previous to mashing is ground or crushed, to render the husks pervious to the water, either by millstones or crushing rollers, turned also by machinery connected with the first mover. These rollers are about 18 inches in diameter, and 2 feet 6 inches in length, and are situated at such a distance that only a piece of thick brown paper can be passed between them. Immediately above these is a third roller, which has a number of deep flutes or cavities cut in it from one end to the other, and these, as it revolves, become filled with malt from the hopper above, and which it delivers into the two rollers: these, being in motion, take it between them and crush the grain flat. By means of this feeding roller the supply of malt to the crushing rollers is regulated and preserved uniform, which is essential to prevent the latter from becoming clogged or filled up. When the malt has passed through the rollers it is of course found completely broken, but very little of it is cut into flour, for the husks of the malt, although crushed sufficiently to admit the water, still prevent the flour being separated, which is considered to be a great advantage over the method of grinding; because that produces a quantity of flour which is the richest part of the malt, but when it is ground and separated from the grain it does not produce so much extract in the mash-tun as when it is preserved in the grain, and the husk sufficiently broken. This is because the flour, when immersed in the water and wetted, forms a sort of paste; this at first absorbs a considerable portion of water which will not afterwards quit it, so that very little extract is obtained from that portion of the malt which is separated from the grain in the form of flour. It may be observed that the malt being brought to the premises in waggons is raised to the

upper floor of the building in sacks by the usual lifting apparatus, as described under Flour-mills. Here it is emptied through holes in the floor in the great malt store lofts, whence it is passed, when required, through shoots to the rollers above mentioned.

Returning again to the malt-crushing rollers, the grain in passing through these fall into a large chest, whence it is conveyed to the malt bins situated over the mash-tuns, by the motion of an inclined screw, somewhat resembling the Archimedean screw, by which it is raised to the point required. The screw itself is formed of thin iron plates bent into a spiral, and fixed by nails to a wooden axle which revolves with the mill. When the malt is required for mashing, it is let down from the bins through sluices or shuttles in the bottom of it, and curtains are hung round from the bin to the edge of the tun to prevent loss from the dust or flour of the malt flying into the air.

The water being heated in the copper is conducted by a pipe to the mash-tuns by the means which will be described as we proceed, and is there kept in constant motion by the machinery, also to be described, in connection with the first mover; and after this process has been continued a sufficient time, the extract or wash is drawn off from the mash-tuns into others beneath them, which are called the lower or under backs, where it remains only till the coppers are ready to receive it again to be boiled. It is then forced by pumps, worked either by horse or steam power, into what is called the copper back, which is a shallow cistern placed above the coppers, or into their pans, which are vessels placed over the coppers, their contents receiving heat from the steam raised by the boiling of the copper itself.

(1127.) This will be understood by referring to plate lxxxvi. fig. 4, which is a section of the close copper now commonly used in breweries. A A is the fire-grate, B B C the copper itself, containing from 200 to 500 barrels. Its top is a dome, having a cylinder G rising from it. F F is the pan erected on the top of the copper, enclosing the dome C within. This pan is heated by steam rising from the cylinder G, and thence descending by pipes d d down into the liquor, and bubbling up through it. The heat communicated through the dome also assists in heating the contents of the pan. In the head or cylinder G are two valves, which are kept shut by steelyards and weights; but these being opened, the steam of the copper is allowed to escape through a pipe into the open air. E is an iron door to allow entrance into the copper, and also to admit the hops. It is situated in the top of a cylinder rising from the dome, and is fitted so close by grinding, that it is steam-tight when shut, and forced down upon its seat by a screw. Two flues proceed from the fire-grate at the further end, and conduct the flame and heated air round in opposite directions, as shown at D D, to the chimney, which is placed over the fire doors, and thus the heat is applied to the sides as well as to the bottom of the coppers. This, as the figure shows, is made concave beneath, to allow a greater action to the fire. The chimney is open at the bottom, and therefore the draught it occasions through the flues is only by the lateral action of the current of air in the chimney; but this draught can be cut off when it is required to damp the fire. In some breweries doors are provided to shut up the bottom of the chimneys, and thus increase the draught by compelling all the air which enters the chimney to pass through the fire-grate,

Mechanical
Processes.

Manufac-
tures.

and thence by the flues into the chimney. This causes the copper to boil much quicker; but the violent heat soon destroys the bottom, by burning or melting the metal. When the hops are boiled in the copper, they are kept in constant motion, to prevent their lying upon the bottom and burning it. This is done by a machine called the *rowser*, contained within the copper: it consists of a vertical spindle *e*, in the centre of the copper, which at its lower extremity has a cross arm *g*, curved, to correspond with the bottom, and from this a number of loops of heavy chain are suspended, to drag round upon the copper when the spindle is turned. By this means the hops are raked over and continually disturbed. The spindle passes through a stuffing-box in the centre of the top *G* of the copper, and is turned round by the wheel *f*, engaged with another upon a shaft receiving motion from the engine.

The copper is provided with a float, to show the height of the liquor within it. This consists of a strong wire passing through a tight stuffing-box in the top of the copper, suspending a stone at the lower end of it. From the upper end of the wire a line is conducted over pulleys, which has a ruler or rod divided into feet and inches suspended from it, with a weight greater than the weight of the stone when it is suspended in the liquor, but less than the weight of the same when it is drawn up out of the liquor. In this situation the stone will always be at the surface of the water, in the same manner as if it floated, and will show the height of the liquor in the copper. There are several pipes and cocks belonging to the copper, which are as follows: a pipe leading from the liquor back to introduce the water into it; this has a cock formed of two passages, one for admitting it to flow into the pan, and the other for conveying it by a short pipe into the copper itself, and the handle being turned in one direction or the other shows which way the liquor will run, and turned in another it will be stopped altogether. There is also a hole in the bottom of the copper back, through which the contents run down into the pan. This is closed when requisite by a plug, and near it is a pipe leading down through the pan into the copper. This is closed by a valve which can be opened with a lever and screw, when it is required to convey the wort from the copper back into the copper itself. There is also a valve which communicates at once from the pan down into the copper. From the bottom of the copper is a large cock with a pipe, which runs horizontally over the mashing-tuns, and in every one a branch of the pipe descends below the bottom of the tun and then turns up, with two or three small branches leading to different parts of the bottom. By this means the hot water is admitted from the copper into the tun and diffused pretty equally through the whole mass of the malt. Moreover, to assist in this essential particular, the tun has a false bottom full of holes, on which the malt lies, and through which the water rises in all parts at the same time.

Different
Patents for
brewing
coppers.

Before quitting this part of our subject, it may be well to say a few words more relative to the copper. We have described it as closed, which it is now in all large breweries. They are found to effect a great saving of fuel, and at the same time to prevent in a great measure the waste of the saccharum and flavour of the hops which passed off with the steam in the old open boiler, as was obvious from the strong scent of those substances diffused from a large brewery to consider-

Mechanical
Processes.

able distances. In the close copper, the steam being passed through the liquor contained in the pan, the above substances are in a great degree condensed and retained in the liquor. At the same time the liquor in the pan is heated, and, being let down into the copper as soon as the other liquor is run out of it, it is quickly boiled, thereby saving much time and fuel. Mr. Goodwynne, whom we have spoken of as having been the first brewer who employed a steam-engine for such works, was also the first to introduce the use of the pan over the copper for the purpose of heating one liquor by the other. This was done as early as 1780, but the steam did not in this case pass through the water. It was about five years later that the steam pipes were introduced by Mr. Bramah, at Hartford's brewery.

Since that time various Patents have been taken out for improvements in brewing coppers. Mr. Richard Hares took out one in 1791 for the construction of a steam head to the copper, but the Patent was set aside by a trial in the Court of King's Bench, on the ground of not being a new invention. In the use of a large brewing copper great attention is requisite, in taking care that the copper is never empty whilst the fire is burning; for, in a few minutes, the bottom of an empty copper would be melted by the intensity of the heat. The fire may always be immediately damped by opening the fire-hole and chimney doors. The cock is opened, and as soon as the brewer can see the bottom of the copper, he lets down the contents of the pan; frequently it is found necessary for the men to go down into the copper and scrape away all the fur which adheres to it from the stony matter contained in the water; for if it was allowed to accumulate for a few days, it would prevent the water from coming into actual contact with the metal, which would, in that case, be quickly melted or burnt through. The copper plates are not less than three inches thick in the centre of the bottom, but diminishing to one inch thick against the flues. They are united by rivets two inches in diameter, and with heads five inches in diameter. When it is required to repair a copper, a new plate is put into its place while red-hot, and hammered down to fit the edges of the plate with which it is to be connected. The plate is then heated again, and holes punched through it in the proper places for the rivets, which are put in red-hot while the plates are cold; they are introduced through the holes from the lower side, and a workman, standing upon the grate, has a hand-jack, which he screws up under the head of the rivet to hold it fast in its place, and immediately three men within the copper batter down the end of the rivet with the utmost expedition. In such thick plates it is almost impossible to get the ends quite close; but the contraction of the rivets in cooling draws the plates together so forcibly as to make them nearly tight, and the leaks cease as soon as the fire is lighted. The very great expense of these repairs, and the loss occasioned by all the works being stopped, render any form of the fire-place which tends to preserve the copper of very great importance. An improvement in the construction of fire-places was made by Mr. Woolfe, who applied it to the coppers at Messrs. Meux's brewery. The same ingenious engineer also erected at the same works an apparatus for heating water by the waste steam which passed off from the coppers. This is described in Nicholson's *Journal*, vol. ii.

Another Patent was taken out by Dr. Sharman, which

tures.

Mashing-
tun.
Pl. lxxxvi.
Fig. 5, 6.

is a cylinder laid with its axis horizontally having flues for the flames passing round it after the manner of a screw, the steam of the copper being condensed in a vessel for the purpose, and the product returned to the copper. Mr. W. Ker had also a Patent taken out in 1788 for a similar manner of condensing the volatile part of the malt and hops.

(1128.) *Mashing-tun*.—The next important machine in the process of brewing we have to describe is the mashing-tun. This is commonly a large wooden vessel, formed of vertical staves bound by iron hoops; but it has lately been made of cast iron in our larger brewing establishments. It has a false bottom, to which allusion has already been made, pierced with a great number of small holes to admit the liquor to pass from the bottom, where it is admitted up through the malt. It has been already stated that the water is brought by pipes from the copper, and delivered at the lower part of the mash-tun under the false bottom, whence it forces its way up through the malt; and when it appears above it the malt (technically the goods) is stirred up to expose every part to the action of the liquor. This was formerly performed by manual labour; the men first using long rakes to level the heap of malt, and afterwards rowing the mass with large oars. But the present extent of the London breweries would render this mode too slow and expensive. Mashing machines are now, therefore, generally adopted. Various contrivances have been had recourse to and adopted at different breweries, but the following for a cast-iron mash-tun, by Mr. Cooper, is perhaps the most effectual.

This machine is represented in fig. 5, 6, plate lxxxvi., the former being a plan and the latter a section of the mash-tun and mashing machine; but, to save room, only one half is represented. The reader will, however, readily imagine another half to each figure.

AA, fig 6, is the level of the stage floor in which the mash-tun is placed; BB is the tun, formed of a number of cast-iron plates screwed together, the disposition of which at the bottom is shown in the plan, fig. 5. The vessel is supported upon eight cast-iron columns DD, which are united at their upper ends by the cast-iron frame E, which confines them in a vertical position, and connects them with a central column, fig. 6. This is cast hollow to form the continuation of a pipe G, which brings the liquor into the tun from the copper as already described. There are branches to this pipe for distributing the water under the false bottom, which arrangement has also been referred to.

Fig. 7, 8.

In the centre of the tun is set up a vertical axis K, which is turned round by wheelwork communicating with its upper end, as in fig. 7. Upon this axis are two bevelled wheels *a b*, giving motion to the mashing engine. These wheels turn two horizontal axes, L, M, extending from the centre to the circumference of the tun. The former has four wheels upon it, over which four endless chains pass, as also over another horizontal axis N, near the bottom of the tun. Upon this endless chain cross pieces of iron, *d*, are fixed, having teeth in them, as shown in the upper and lower piece, fig. 6, and also in profile in fig. 7. These, as the chains revolve by the action of the wheel *b*, raise up the malt from the bottom to the top of the tun. That this may be performed in all parts of the tun, the frame containing the axes L, M, N has a progressive motion round the tun. This is thus effected: on the curb or upper edge of the tun is a range of teeth *o, o*, fig. 5; these are

engaged by an endless screw, which is mounted in a frame P, fig. 8, and which receives its motion by means of wheelwork connected with the axle above described, and the frame is thus made to have a slow progressive motion of rotation round the tun.

R is the under back, which is placed between the iron columns upon brickwork supported on bearing piles. This is also formed of cast-iron plates in the same manner as the mash-tun above described. The use of this vessel is to receive the liquor from the mash-tun after the operation of mashing is completed, and from which it is drawn off again by pumps and conveyed to the copper to be boiled with the hops, after which it is transferred to a broad, shallow vessel to be cooled; it is then fermented, and ultimately cleansed and placed in the proper store vats till called for.

We have confined our description of the mash-tun strictly to one in cast iron; but many different forms have been given to this important brewing vessel: of these, one was erected at Goodwynne's, the figure of which was that of a half cylinder placed horizontally, and on the central line or axis an iron shaft was fitted and turned round by wheelwork from the steam-engine. It had several iron arms fixed perpendicularly upon it at different parts of its length, which, as the shaft revolved, swept the whole contents of the tun; and, having teeth in them, they performed very effectually the mashing process. These arms were not all fixed on the same side of the axis, but were arranged at equal angles round it, so as to dip into the malt in succession; and this had a tendency to accumulate the malt towards one end, but the motion could be reversed which carried it back again.

Another mashing apparatus was constructed by Mr. Silvester for Messrs. Clowes. This consists of a vertical spindle in the centre of the mash-tun; and upon this an iron arm, of a length sufficient to extend across the diameter of the tun, slides up and down through the depth of the grist. The arm is provided with teeth projecting from one side of it like a rake; and these teeth are so contrived that when the arm descends they hang down vertically, and their points penetrate the goods without disturbing them; but when the arm reaches the bottom of the tun, the teeth are turned by the machine so as to be horizontal, and are then drawn up, during which action they raise a portion of the grist from the bottom to the top. The next time the arm descends, it is turned round with its spindle a few degrees, so as to take a fresh portion of the tun; and in this manner its action continues till, in about thirty or forty strokes, it completes its revolution round the tun. This construction admits of the mash-tun being covered close over by large doors, a circumstance of great importance for retaining the heat.

Various other machines for facilitating the process of mashing have been projected and patented, which our limits will not admit of describing; nor is such a description actually necessary, our object having been simply to give a general idea of the principles on which this important national beverage is obtained in our larger establishments.

(1129.) The extent of the brewing trade will be seen by the following statement of the quantity made and the revenue derived from the duty on beer from 1820 to 1830. The duty has been since repealed, and, of course, the quantity brewed largely increased.

Distilling.

Distilling, first invention of, by Villeneuve.

(1130.) The Art of distilling, with a view to the production of spirituous liquor, seems to have been the invention of a Frenchman in the XIIIth Century of the name of Villeneuve, who was a distinguished chemist or alchymist of that date, from which time to the commencement of the present century slow but progressive ameliorations were introduced; but since that time the progress of improvement has been very rapid and important. M. Dubrunfaut, in his Treatise on Distillation, gives also the honour of the first great step towards the modern practice to another Frenchman, M. E. Adam, whom he states to have been "an obscure person, unacquainted with Science, and ignorant of the Art he undertook to improve;" but who, notwithstanding, established a new system, "and, with a giant's pace, arrived at that point which the most profound geniuses had never been able to attain, after the continued labours of many centuries." If, he continues, "Raymond, Lully, Portas, Lavoisier, Meusnier, or Fourcroy had made such a discovery, one might have admired their genius without being surprised at their science; but that a man who had not even the first notion of the Art in which he was engaged, and who had not the least experience in the manual operations, should rise all at once, and at his first trial ascend to the acmé of the science, is certainly extraordinary."

Great improvement by Adam.

This great step, according to M. Dubrunfaut, was made in 1801; since which time, however, much has been done to render still more perfect the Art of distillation, although the principle has remained unchanged. The processes or modes of distillation may be classed under two heads. In one, the method is to cause the evaporation, by means of heat, of the mixture of two liquids, to receive the vapour that rises from the one into a vessel in which they are condensed by cold, and to collect the liquor thus condensed. In the other, the method consists in causing the same evaporation of the mixture of the two liquids, to receive the vapours in a vessel where, by the assistance of caloric prudently administered, the whole undergoes a complete analysis, with a separation into two distinct parts, whereof the one which is spirituous is collected on one side after being condensed by cold, and the other part, which is

Different modes of distillation.

aqueous and condensed during the process, on the other. Mechanical Processes. The first mode of distillation was generally followed till about the beginning of the present century, when the great revolution in this Art took place by the discovery of M. Adam; which consisted, however, principally in availing himself of Woulfe's apparatus for the distillation of wines, described in the *Phil. Trans.* for 1767, and the economical method of obtaining heat recommended by Count Rumford. It is necessary, therefore, before we attempt any description of the improved method, to make the reader acquainted with what is commonly known under the denomination of Woulfe's apparatus for distillation; which consists principally in causing the vapours as they arise to pass through successive vessels partly filled with water, and to cause the gas to pass through as many such as are requisite before it is allowed to escape; and even at the last it may be detained by connecting the tube from the last vessel with a gas holder. This had reference principally to distillation in a small way; but Adam applied it in the large way for alcohol from beer or wine, by bringing a tube from the capital of the still into a large copper recipient; by another tube this was joined to a second recipient through a series of four vessels arranged according to the plan proposed by Woulfe. The last vessel is then made to communicate with the worm of the first refrigerator, by which means the body of the still and the two recipients nearest to it are charged with the wine or fermented liquor, and, when ebullition takes place in the still, the vapour arising from it soon communicates the boiling temperature to the liquor in the two recipients; from these the volatilized alcohol will rise and pass into the third vessel, which is empty. After imparting a certain heat to it, a portion of the finer or less condensed spirit will pass into the fourth recipient, and thence in a little time into the worm of the refrigerator. The wine round the worm will also acquire heat, but more slowly; therefore the vapour, which in consequence may pass uncondensed into the first worm, is conducted into a second surrounded with cold water. Whenever the still is worked off, it is replenished by a stop-cock from the nearest recipient, which in its turn is filled from the second, and the second from the first worm tub; it is thus evident that, by keeping the third and fourth recipients at a certain temperature, alcohol may be formed of any degree of lightness at the remote extremity of the apparatus; by this means a great economy is effected in the expenditure of fuel, and the flavour of the spirit much improved. Several stills on this principle have been constructed at Glasgow for the West-India distillers; but the Excise laws do not permit their employment in the home trade.

Adam's principle of distillation.

It has been stated that the English distiller is not at liberty to avail himself of this form of still; the process of distillation in this Country is therefore conducted on a different principle to that above mentioned, and it will be proper before we proceed further to give some account of the English process. We may observe, generally, that all distilling vessels are either alembics or retorts; the former consists of an internal vessel called a curcubile, designed to contain the matter to be operated upon, and has an upper part fixed to it called the capital or head, in which last the vapours are condensed by its contact with the surrounding air, or by the assistance of cold water, enclosing the head in a vessel called the refrigerator or cooler. From the lower part of the capital or still-

tures.

Retorts.

British
mode of dis-
tillation.
Wright's
Patent.
Pl. lxxxvii.
Fig. 1.

head a tube proceeds called the nose or beak, through which the vapours, after condensation, are made to flow into a vessel called the receiver, which is usually spherical.

Retorts are a kind of bottle formed in a small way of glass or earthenware, and in the large way of metal, the bottom part spherical and the upper part gradually diminishing into a neck which is turned on one side.

Various means have been had recourse to in applying heat in distillation, depending upon the nature of the apparatus employed as well as upon the substance to be distilled; but the common still, being formed of metal, is immediately exposed to the naked fire, since from its tenacity, and its property of conducting heat with facility, it is not liable to crack, which is not the case with glass or earthenware.

(1131.) The above general description will be better understood by referring to plate lxxxvii. fig. 1, which is the representation of a Patent still by Mr. Wright, engineer, in the Kent-road. The still is of metal, as usual; and has an internal division *a a*, which forms the still into two compartments; these are both filled with wash or other liquor intended for distillation. The still is heated by the furnace below, and the vapour from the lower compartment is driven through the tube *b*, and descends by the bent pipes *c, c* into the wash of the upper compartment; from the tube *b*, without the bent pipe, the vapour may be dispersed above the surface of the liquor within the still, by the intervention of a plate placed over the tube *b*, and a pipe *d* to the vessel of water, whence it descends again by the pipe *e* into the upper compartment of the still; by this means a partial condensation will have been effected of the grosser vapours which have arisen from the lower compartments, and the lighter or uncondensed vapour will pass off through the perpendicular pipe *f* to the condensing apparatus, where it finally becomes spirit. The heat of the furnace being continued, the vapour from the upper compartment of the still will also be driven off and pass through the pipe *f* to the condensing apparatus. A small pipe *g*, with a stop-cock, is inserted into the tube *b*, and carried through the vessel of water, by which a small quantity of the vapour from the lower part of the still may be admitted into the glass vessel *h*, for the purpose of ascertaining the quality of the vapour. When the spirit is out of the lower compartment of the still, and the upper compartment reduced to the gravity intended, the spent liquor below is to be drawn off through the cock *i*, after which the valve *k* may be opened to admit the liquor from the upper to the lower part of the still, and the succeeding charge is drawn from the cistern *l*, through the pipe *m*, to the upper part of the still. The condensing apparatus consists of two cisterns placed one within the other; the inner one *l*, which should be made with copper, is filled with wash, or other liquor intended for subsequent distillation, by means of the pipe and funnel *j*. This vessel should at least contain two charges for the upper compartment of the still; the outer vessel *n n* may be made of wood, and must be charged with water circumscribing the inner vessel; but when the former vessel is attached to other stills, the outer one *n n* may be dispensed with and the pipe *o o* attached, which must communicate with another condenser. The vapour passing from the still through the pipe *f*, as above described, proceeds to the spiral condensing pipe *p*, which passes several times round the vessel *l*, and, the vapour being cooled and condensed in

its progress, finally collects in the form of spirit and is drawn off through the pipe *o*; *q* is a pipe inserted into the head of the vessel *l*, with a light valve opening upward for admitting any vapour into the condenser *p* which might arise from *l*; but this, at the same time, prevents the passage of any vapour from the still through the pipe *f*; a water pipe *r* is attached to the cistern *n* to carry off the surplus water. The parts of this apparatus claimed as original are "a vessel to contain wash or other liquor in the progress of distillation, surrounded by a cavity for condensing the water from the still." The apparatus shown at *h* and *s* are glass vessels containing a number of graduated bubbles, of known gravity, for determining the specific gravity of the spirit.

Another improvement made by Sir Anthony Perrier, of the city of Cork, is to cause the liquid operated upon in the process of distillation to flow gradually over the heated surface of the boiler, whilst it continues to give out its spirituous evaporation. The quantity of liquid allowed to be acted upon, or to pass through the still in a given time, and also its velocity, is regulated by the circuitous route in which it proceeds, and by that means the complete operation of the fire upon the whole fluid is ensured without impeding or clogging the spirituous evaporation by aqueous or empyreumatic vapours. By this construction of a still, a continued and uninterrupted distillation, boiling, or evaporation is carried on so long as the supply of liquid is furnished and the fire kept up. Fig. 2 is a view in profile of the section of a still or boiler made on the improved principle, of copper, or of any other suitable material, and fig. 3 is a plan of the same. The bottom of this boiler is divided by concentric partitions, which stand up as shown in fig. 2, sufficiently high to prevent the liquor from boiling over; these partitions have openings from one to another at opposite sides, so as to make the course a sort of labyrinth; *a* is a reservoir of liquor prepared for the operation; *b* is a pipe or tube descending from the reservoir, and conducting the liquor to that part of the boiler marked *c*, which is the commencement of the race, from which the liquor flows through the channels, as shown by the arrows, fig. 3, progressively traversing the whole surface of the bottom, so that the full effect of the fire is exerted upon small portions of the liquid, which causes the evaporation to proceed with great rapidity. The residue of the liquor then passes off by the discharge pipe *d*, contrived to slide for the purpose of regulating the quantity and depth of the fluid intended for the still; and this pipe should be in such proportion to the admission pipe as to cause the perfect distillation of the liquor in its passage to the regulating tube. The spirit which rises in the head of this improved still will be found much stronger and purer than that obtained from stills of the ordinary construction, where the spirituous vapour is much mixed with aqueous matter and other impurities. The channels may be extended to any length required over a bottom of any dimension by contracting their breadth. Stills upon this principle may be made of all sizes and shapes, round, square, or otherwise; and the partitions may be placed in concentric or eccentric circles, with openings on their sides, at such distances as shall cause the liquor to flow over the most extended surface of the bottom; or, the still may be square, with angular partitions ranged as a labyrinth, or in any other manner, so as to cause the run of the liquor to be greatly extended over

Mechanical
Processes.

Fig. 2, 3.

Manufac-
tures.

the surface of the boiler. The bottom of these stills may be either flat, concave, convex, or of any other form, and the entrance of the liquor into the still, and also its discharging aperture, may be at the side, in the middle, or elsewhere, as circumstances may dictate. Boilers or evaporators may be made upon this plan either with or without heads, and their capacity of working may in all cases be increased by placing layers of pipes connected thereto within the flues, between the still and chimney, which pipes may be bent or coiled in a serpentine direction, or in any other position, and the liquor to be operated upon made to pass through them previous to its entering the still; thus the operation may be advanced to any required state of forwardness. Stills of the above description, particularly if made square, may be divided internally into several, each having its separate head and condenser, by which arrangement the spirit condensed from the first may fall into the second to be again operated upon, and so on to the third, whereby a rectification may be carried on to any degree at one operation and by one fire. In the still shown in fig. 2 a set of chains are seen suspended from the bar *ee*, supported by a centre shaft, that may be put in motion by a toothed wheel and pinion actuated by a crank or winch. These chains hang in loops, and fall into the spaces between the partitions, to sweep the bottom of the still as the shaft revolves; and thus they prevent the materials acted upon from burning when of a thick glutinous nature, as turpentine, syrups, &c.

It is impossible, of course, to describe the several forms which the still takes in the hands of different constructors, but the above will give a general idea of the process; other forms of British stills are described by Mr. Sheridan in his translation of Dubrunfaut, to which we have been indebted for the above.

Method of
distilling
rum in the
West
Indies.
Pl. lxxxvii.
Fig. 4.

(1132.) *Distillation of rum.*—The following description of an improved still constructed by Messrs. Shears and Son, as proposed by Mr. Corty, is given by Mr. Porter in his *Treatise on the Culture of the Sugar-cane*. The still is represented in plate lxxxvii. fig. 4, where A is the body of the still, B the still-head, which is made very capacious in order to guard against the accident of boiling over through mismanagement of the fire; C, C, C are discs, or plates of copper, placed very near to the tops of the boxes D, D, D, which have a supply of water on their upper surfaces, brought from the worm tub through the pipe E to the top of the upper box, and thence, through the pipes G, G, G, to the tops of the second and lower boxes, and, lastly, to the drain or sewer. The supply of water, escaping from the side opposite to that on which it enters, occasions it to flow over the whole surface of each box, which will thus be kept at nearly an equal temperature. When the wash is made to boil, the vapour, filling the head, strikes against the colder surface of the lowest disc C, and will at first be all condensed; but when the operation has been continued sufficiently long to heat the water contained in the lower box D beyond the boiling point of alcohol, the aqueous vapour alone will be there condensed, and the spirituous vapour will pass between the edges of the disc and the side of the box to the second box, and so on to the third, whence it passes, in a highly rectified state, to the worm of the condenser. When the still is fairly in operation, it is recommended to regulate the supply of water to the boxes by means of the cock F, so that in the upper box it may indicate the temperature of about 145° Fahrenheit, in the second box about 160°, and in the lower box

about 180°. The relative temperatures of the two lower boxes may be found to vary somewhat; but this is of no consequence, it being the heat of the water in the upper box that regulates the strength of the spirit by allowing more or less of aqueous vapour to pass over to the condenser. The temperature here mentioned of 145° is found, in the use of this apparatus, to condense so much of the aqueous vapour that the spirit passes on to the condenser nearly 50 per cent. over proof; but as it is found that rum of this strength does not possess its peculiar aromatic flavour in an equal degree with spirit of from 30 to 35 per cent. over proof, it will, perhaps, be thought desirable so far to depart from the instructions of the manufacturers as to allow the water in the upper rectifying box to acquire a higher temperature; these, however, are details which a very short experience will suffice to regulate. To the lower end of the worm a gas apparatus is affixed by a brass swivel joint screw H, the condensed spirit speedily fills the bent tube I, causing the separation of the carbonic acid gas which passes through the pipe K to the vessel L; this contains water at about two inches higher level than the bottom of the tube K; through this water the carbonic acid gas will escape preferably to passing through the bent tube L, where the resisting fluid column has a greater depth. The figures 1, 1 represent the solid masonry in which the still should be set; 2 is the fire-place; 3 the bottom plate which supports the mouth-piece; 4 the ash-pit; and 5, 5, side flues leading to the chimney.

Mechanical
Processes.

The specific gravity or strength of rum is commonly ascertained in our colonies by its capability of floating hollow bulbs of glass which are numbered according to their weight; but this method is by no means accurate, unless allowance is made for variations of atmospheric temperature, which materially affects the apparent strength of spirits. These bubbles are differently numbered, and when the thermometer stands at 70°

(1133.) It is much to be regretted that the duty on spirits has rendered it necessary to prescribe to the British distiller certain forms and processes to avoid impositions on the revenue, so that he has not been at liberty to avail himself so much as other persons of the advantages which Science has conferred on nearly all our manufactures. Amongst the many plans suggested for the improvement of distilleries, one of a very curious nature, which failed from the above cause, was proposed by Mr. Birch, of Roscrea, which was calculated to obviate the difficulty of procuring fuel, and to work the still much more advantageously by the application of steam than by the use of either turf or coals. In carrying on this experiment, the liquor in the still was boiled by the aid of steam raised in a boiler prepared for that purpose, and conveyed by a pipe which communicated with the exterior of the still only; but filling up with steam the spaces or interstices made in the formation of the still, and also the space between the still itself and

Distillation
by steam.

Manufac-
tures.

its case, which latter was made of wood, and every part of it exposed to view.

A trial on this apparatus was made before certain Commissioners of Excise at Roscrea. Previous to the trial there were four furnaces independent of the steam-engine, one for the still, and one for each copper, which contains two hundred and twelve superficial feet; but by the proposed plan these were reduced to two, containing only sixty-four superficial feet subject to the influence of the fire. It appeared, moreover, that steam not exceeding two hundred and twenty degrees was able to produce the highest charge of the Excise laws with a saving of four-fifths of the fuel, and the same of all other expenses. The plan, however, was rejected by the Excise on the principle that it would afford facilities to smuggling under the then existing regulations; but since the Act of the 4th of George IV. c. 94., has relieved the distiller from the production of a limited quantity in a given time, this steam method has been thought deserving of reconsideration.

These stills were made of copper: those capable of holding forty-four gallons were about forty-four inches in diameter at the bottom, and about five inches deep; those holding eighty gallons were fifty-four inches in diameter, and about eight inches deep; the bottom was perfectly flat, and about three-eighths of an inch thick; within it there were a number of iron chains turned round by machinery, which, by rubbing against the bottom, prevented the thick matter, which the wash always contains, from adhering to the bottom of the still and catching fire. This might have occasioned the immediate destruction of the still, and the scorched starchy matter would have communicated a disagreeable flavour to the spirits which could not have been got rid of afterwards; there was likewise a circular plate in the inside of the still towards its top, which broke the bubbles which arose during rapid distillation, and lessened the risk of the still boiling over, or *running foul*, as the distillers term it, consequently the distiller was enabled to put a greater charge of wash into the still than it would have been in his power to do had this circular plate been omitted.

The present stills, though much larger in size, imitate the others in the great diameter of their bottom. The top of the still ends in a kind of tube bent downwards, and connected with a tin tube which makes a number of revolutions in a large vessel filled with water, and therefore called the worm. This large vessel is called the *refrigerator* or cooler, and care is always taken to keep its situation in a state to do this by means of a stream of water constantly flowing into it. The wash being put into the still, and the top fixed down, heat is applied to the vessel till it is made to boil, when spirits, being more volatile than the water, go over first in the state of steam, and are condensed into a liquid as they pass through the worm. The first portions that come over are very strong, but the strength diminishes as the process proceeds: the distiller continues the operation till the liquid which flows from the worm is as heavy as water, or till the quantity of spirits remaining are not considered as a compensation for continuing the process any longer. The strength of the liquor proceeding from the worm is ascertained by a small hydrometer, with which it is tried every now and then, and whenever a certain mark on the instrument coincides with the surface of the liquid, a cock at the bottom of the still is opened, and what remains in the still is let off:

this is called the *spent wash*; it is a muddy brown liquid, and still retains a quantity of undecomposed saccharine matter which has been frequently used as food for cattle. To prevent the still boiling over, which is apt to take place towards the commencement of the distillation, it is usual to throw a piece of soap into the vessel along with the wash; the oily matter which the soap contains, being spread on the surface, forms a thin coat, which breaks the large bubbles when they rise, and thus prevents the wash from swelling beyond its usual bulk: butter would be less liable to communicate a disagreeable flavour, and so perhaps would hog's lard. It is impossible to lay down any rule with respect to the strength of the weak spirit obtained by this first distillation; it must depend partly upon the strength of the wort, and partly on the attenuation which has taken place during the fermentation, but chiefly upon the attention of the distiller to distil off the whole of the spirituous portion of the wash. The low wines are put into the still and subjected to a second distillation, which in Scotland is called *doubling*. The first portion which comes over is a milky liquid known by the name of *foreshot*; the third portion is called *feints*, which are mixed with what is called the low wines and distilled again. Another distilling apparatus is represented in fig. 5, the operation of which is sufficiently obvious without a verbal description. Mechanical Processes. Pl. lxxxvii. Fig. 5.

Method of making Crayons.

(1135.) Crayon is a general name for all coloured stones, earths, or other mineral substances, used by artists in designing or painting in pastel, and the same is still applied when these substances are first reduced to powder and re-formed for use. As considerable difficulty is experienced in obtaining good crayons, M. Lomes, a French artist of considerable note, undertook to make a variety of experiments with a view to obtaining them in the greatest perfection, an account of which is published in the *Annales de Chimie*. Red crayons are composed of the softer kind of ochre or reddle, which is an oxide of iron mixed with an argillaceous earth

* The reduction in the rates of duty on British spirit was, in 1823, from 6s. 2d. in Scotland, and 6s. 7d. in Ireland, to 2s. 4½d. per Imperial gallon; 1826, in England, from 10s. 6d. to 7s. per gallon.

Manufactures.

called hematites or bog-ore. This must be incorporated with some agglutinating substance, such as gum, glue, or rosin, to which is sometimes added soap for softening the composition; but instead of reddle other red oxides of iron, as colcothar of vitriol, &c. are used. These should be selected from those which are the softest to the touch, and of a lively colour, avoiding any mixture of clay, which produces a yellow tint. The ochre thus selected should be ground with pure water on a marble slab, as in preparing colours for painters, and moistened only with sufficient water to make the stone slide. For preparing a large quantity, the reddle must be pounded and sifted through a fine sieve, then diluted with a large quantity of water in a trough, where, after being well stirred, it should be left for a few minutes to settle, that the grosser particles may subside to the bottom. The water, strongly impregnated with the finer particles, must then be poured off and allowed to settle for twenty-four hours. When the clear water has been poured off, a fine sediment will be obtained, which must be again pounded and washed; and this process must be repeated till the whole is reduced to the utmost fineness. The gum, glue, or soap necessary for giving to the crayons a due degree of solidity must be separately dissolved, the solution carefully mixed with pounded ochre or reddle, and the water evaporated by exposure to the sun or to the heat of a gentle fire, taking care frequently to turn the paste till it has acquired a consistence somewhat harder than butter. The crayons are then to be formed in the moulds, which may be done two ways: first, by spreading out the paste on a board, in which grooves are cut rather broader at the top and round at bottom, and of any length, size, and depth, according to the proposed bulk of the crayons; or otherwise, which is the better method, by forcing the paste through a pipe or funnel of an orifice equal to the size of the crayon. The paste thus formed may be left to dry in a cool place under the shade, in order to prevent cracks, which a more rapid desiccation would produce. When the rods are dry they are to be cut into a proper length, and the edges should be taken off; after which they must receive the first cutting, in order to give them a blunt point. The last operation is that of scraping them, for the purpose of taking off the hard, outward coat formed on the surface in drying, and which would prevent their making any marks. It may be necessary to rub a small portion of oil into the grooves of the wood that the paste may not adhere too closely to the moulds. Gum arabic and isinglass are the two best substances for mixing with the powder. The gum and soap may be dissolved in cold water; but the isinglass must be cut in small pieces, put into hot water, and dissolved in *balneo mariæ*. These solutions should be well diluted with water that they may be made to pass through a hair sieve, in order to remove any foreign particles. As it is difficult to incorporate the paste with the isinglass, they must both be heated and mixed over a fire with a heat equal to that of boiling water: it is necessary to mix the paste before it is moulded. The best mode is to beat it with a pestle or mallet, and so pound it again for some time before it is to be put into the moulds. Soap is not required but for those crayons in which gum is used. The best means to prevent waste during the operation will be to fix by experiments the quantity of water and of ingredients which the pounded reddle and the solutions form before the mixtures are made. The following statement will serve this purpose. 1. Dry reddle, or red

oxide of iron, 1 ounce; gum arabic, dry, 18 grains: crayons thus made are very friable, but they may be used for large designs. 2. Reddle, &c. 1 ounce, gum 21 grains, will yield strong crayons, rather friable, but excellent for large drawings. 3. Reddle 1 ounce, gum 24 grains, or rather $25\frac{1}{2}$ grains, will give smooth and solid crayons, the best for common use. 4. Reddle 1 ounce, gum 27 grains, will produce soft firm crayons fit for drawings which require delicacy and precision. 5. Reddle 1 ounce, gum 30 grains, will yield very firm crayons fit for small drawings which are to be highly finished. 6. Reddle 1 ounce, gum 33 grains, will give very hard crayons which cannot be used without some force. This is the greatest quantity of gum that can be employed in their composition; with more they would be useless. 7. Reddle 1 ounce, gum 22 grains, white hard soap 30 grains. Crayons thus formed have a somewhat browner cast than the former. Their consistence is good, and they may be easily cut. When crayons have soap in their composition, all the strokes made by them have always a shining appearance, if the touches are repeated somewhat too strongly. These crayons perfectly resemble those of Desmarest. 8. Reddle 1 ounce, isinglass 36 grains, produce crayons of a brilliant colour and excellent for use. With less isinglass they become brittle, with more too hard.

Mechanical Processes.

(1136.) *Crayons for tracing on glass.*—This is an invention of Mr. Howlett for perspective drawings. The instrument consists of a plate of clear glass fixed in a frame, and set upright on a tripod stand so as to bring it on a level with the eye of the artist. From the top of the tripod projects horizontally a light frame with a hole at the end for the purpose of supporting in a vertical position a pin, at the top of which is a small perforation, through which the artist looks while he traces on the glass the objects seen through it. So far the instrument does not differ in any material respect from those usually employed for this purpose. But as glass is not capable of receiving the traces made by the pencil, it is necessary to cover the surface of the glass with some substance, at the same time as transparent as possible, and capable of being marked by a pencil. These conditions, however, have not hitherto been found to be reconcilable. The most transparent paper that can be made is not capable of allowing distant objects to be seen through it with sufficient distinctness, and glass itself, though unexceptionable with regard to transparency, will not retain traces from a black-lead pencil, or from any other of the materials usually employed in sketching. The way in which Mr. Howlett solves this problem is by the invention of crayons capable of bearing a fine point and of leaving traces on the surface of the glass. In the use, therefore, of this instrument, the objects are delineated with the crayon on the surface of the glass, and afterwards a piece of paper is laid over the drawing and is secured by its four corners to prevent it from slipping. The glass with the attached paper is then held up to the light, and the objects already drawn on the glass are traced on the paper with a common pencil. If the paper, instead of being laid on the drawing, is placed on the opposite surface of the glass, the copy will be made in a reversed position, and is thus immediately adapted to the use of the engraver; or the tracing on the glass may be transferred to paper, by laying the paper over the tracing and rubbing them together with an ivory-handled knife. If the tracing paper employed is thick or opaque, so that the lines on

Crayons for tracing on glass.

Manufac-
tures.

the glass are only seen indistinctly through it, a great degree of blackness may be given to them by dusting the surface of the glass over with dry lamp-black, and then rubbing it off with a soft camel-hair brush very lightly applied: the traces made by the crayon being somewhat adhesive, the lamp-black will be fixed on them by the action of the brush, while it is swept off from the rest of the surface. The crayons are made of three degrees of hardness to suit any climate, and are not acted on by water, either fresh or salt. Asphaltum and yellow bee's-wax, in equal proportions, are melted together, and then lamp-black, just sufficient to give it a colour, is stirred in. The mixture is then cast into sticks, and forms a crayon suitable for a temperate degree of heat; but for very hot weather, the hardest kind of heel-ball, lowered with a little tallow, answers admirably. The glass plate, previous to drawing on it, should be rubbed well with a leather, in order to force from it any moisture or dirt, and the artist, while making the drawing, should wear a finger-stall. It is sometimes difficult to bring the crayon to a fine point with a common penknife, for if the edge of this latter is set to the shape of a very fine wedge it will slip through the crayon, and, on the other hand, a blunt edge will break off the point before it has been cut sufficiently fine; but if the knife is set chisel-shaped, the oblique surface being applied next to the crayon, shavings of extreme tenuity may be taken off and a very fine point will be the result.

Manufacture of Steel Pens.

Steel pens.

(1137.) The extraordinary extent of this manufacture renders it necessary that we should say a few words on the subject, although there is nothing very remarkable to describe. The steel is rolled into very thin plates the usual thickness of these pens, in pieces about 4 inches broad and 3 feet long. These are then placed successively under a stamping press, such as we have described under button-making, and pieces of the proper form for the pens are cut out with great rapidity. The nib is then introduced into a gauged hole of the proper form to receive it; it is then pressed into the cylindrical form, and the slit and other openings in the pen formed in like manner: they are then cleaned, and ultimately tempered. The cleaning is performed in a very curious machine. This consists of a tin cylinder about 8 or 9 inches in diameter and 3 feet long, with a hole in the middle of its length for putting in and taking out the pens, which hole is covered by a lid. The cylinder is hung on joints at each end to cranks formed one on each of two axles. These are furnished with a fly-wheel, and one of them with a handle. As this latter is turned, therefore, the cylinder is thrown up and down, and backwards and forwards, each end and every part of course describing a circle, whereby the pens are rubbed one against another, and ultimately come out beautifully bright and clean. This operation is carried on for three or four hours; but many thousand pens are operated upon at the same time.

Quill pens
made by
machinery.

(1138.) *Making quill pens by machinery.*—Short quill pens are sold properly formed for writing, which are cut by machinery as follows. The top and bottom of the quill being cut off, the open piece is run upon a cylinder, on to which it slips easily, and, being placed in a machine, two cutting edges are run along it, one on each side, forming the quill into two semicylindrical

pieces. These are laid in grooves with the round part downwards, and a plane run over the upper side or edges to make them smooth. They are then cut into proper lengths, two or three being formed out of each length, that is, four or six out of each quill. Each piece is now brought to the nibbing machine, which is a kind of cutting press, and each is lastly finished off with a few touches by hand from a sharp penknife.

Mechanical
Processes.

Black-lead Pencils.

(1139.) The best pencils of this kind are made from a natural ore of plumbago obtained from Borrowdale, in Cumberland; but the more common sort from an artificial compound of plumbago dust and antimony. The lumps of pure plumbago, when scraped and freed from dirt, are of irregular form, varying generally in size between that of a walnut and an egg. These lumps are cut into slices of about the thickness of a shilling by a small circular saw, which is put in motion by the workman turning a winch and fly-wheel with one hand, while he applies the lump of ore with the other against a metal face set at a proper distance from the disc of the saw, so as to act as a gauge or stop for producing the proper thickness in the slice. The saw runs vertically, and the ore is applied below it, the workman gradually raising it against the saw till the piece is cut off, when it falls down slice upon slice on a table below, these being of different sizes, from one to two inches in length, and of variable breadths. One edge is now made quite straight, and the insertion of the lead into the pencil commences. First, however, it should be observed that pieces of cedar are cut by a fine circular saw into square prisms of the intended length of the pencil, or rather into such thickness that two of them together form a square, one of them thicker than the other, so as to admit the groove cut to receive the lead to be in one piece only, this groove being ploughed out by a proper gauge plane. The workman takes now one of the slices of plumbago brought to a straight edge, and dips this straight edge into glue, he then inserts it in the groove, and with a sharp instrument makes a cut on each side along the edge of the wood, when by a slight force it breaks off, leaving again a straight edge. This is now dipped again in glue, and inserted at the end of the last piece, and again cut off, till the length of the groove is filled with the lead. The whole upper surface is then smoothed, and the other piece of wood glued on; the pencil is then square and rather rough.

It is now taken to be made round, preparatory to which it is passed along a circular saw set to an exact gauge, and cut also to a certain length. In order to give it its cylindrical figure it is passed through a square hole in an iron or steel puppet of the exact size of the pencil, and forced along by the workman. On the other side of this puppet is the revolving apparatus which cuts the pencil round; it consists of two gauges, and a small plane iron revolving round an open centre. Beyond this is a cylindrical hole in a steel plate; as soon, therefore, as the first end of the pencil is cut round it is forced into this circular hole, and, before the workman has lost the means of pushing it forward at the end that is square, the cylindrical end is pushed through the circular hole, so as to enable him to seize it with a pair of wooden nippers; and it is thus pushed and drawn quite through, and comes out beautifully

Manufactures.

Pencils for pencil cases.

round and polished, the latter effect being produced by the hole being rather smaller than the pencil, whereby the wood is compressed and polished, as above stated.

(1140.) *Cutting leads for pencil cases.*—The pieces of lead for the pencil cases, the original Patent of Mr. Mordan, are cut from slices of plumbago, such as is described above, first into square prisms of proper dimensions for forming the cylindrical pieces, which are then made round by forcing them lengthwise through three different sized circular holes cut in pieces of ruby. In passing through the first hole only the four angles of the prism are taken off; it is then of course octagonal; the next hole, which is smaller, takes off these eight angles, and it then becomes a prism of sixteen sides, and in the next passage through the smaller hole it attains the true cylindrical figure.

The manner of forcing the lead through the several holes is not much unlike that in which the lead is forced up in the pencil case itself; that is, in a piece of metal about three inches long is a hole lengthwise, just big enough to receive the first prism, and at the other end of this is the ruby hole mentioned above. This piece of metal runs in a groove to preserve its direction, and the end of a steel pin, fixed in an upright piece of iron at the proper height, is introduced into the hole into which the lead is dropped, and a boy then presses the movable piece of metal containing the lead against the pin, which forces the piece forward through the ruby hole cutting off its angle as above described. A number being thus cut, he passes them all in the same way through the next, and lastly through the third hole, when they are ready for use.

Glue.

Glue manufacture.

(1141.) This is a substance used in various processes, as in making size, but more especially by joiners, carpenters, and other artisans; the consumption of which therefore is considerable, and some rather large establishments are appropriated to its manufacture. The English is reckoned the best, and is exported to other Countries. This substance is made of the skins of all kinds of beasts, oxen, calves, sheep, &c., or rather from fragments of them, as whole skins are too valuable to be thus employed except in very rare cases, that is, for glue of the best quality.

The materials above enumerated are first digested in lime water to cleanse them from grease or dirt; they are then steeped in clean water with frequent stirring, and afterwards laid in a heap and the water pressed out; they are then boiled in a large brass caldron with clean water, skimming off the dirt as it rises, and it is further cleansed by putting in, after the whole is dissolved, a little melted alum or lime finely powdered. The skimming is continued for some time, after which the mass is strained through baskets and suffered to settle, that the remaining impurities may subside; it is then poured gradually into the kettle again, and further evaporated by boiling and skimming till it becomes of a clear dark brownish colour. When it is thought to be strong enough, it is poured into frames or moulds about six feet long, one broad, and two deep, where it gradually hardens as it cools, and is cut out when cold by a spade into square cakes. Each of these is placed in a sort of wooden box, open in three divisions to the back; in this the glue, while it is still soft, is cut into three slices with a kind of bow, with a brass wire in the place of the string; now the slices are taken into the

open air and dried on a kind of coarse network, fastened in movable sheds four feet square, which are placed in rows in the glue-maker's field; having become perfectly dry and hard it is fit for sale. The best glue is that which swells considerably without melting by three or four days' immersion in cold water, and recovers its former dimensions and properties by drying. If the glue should be injured by frost, or look black and thick, it is necessary to melt it over again. The purchaser may easily detect bad glue by holding it before the light, for if good it will appear of a strong dark colour and free from cloudy and black spots. Carpenters commonly break the glue in small pieces and soak it four and twenty hours in cold water, and then melt the pieces, allow it to simmer very slowly over a fire, and keeping it frequently stirred; when done in this way it becomes, when cold, a firm jelly, which may be cut by any instrument. It only requires to be warmed to be fit for use, and in this state spread over the surface of the wood with a stiff brush; in two or three days the pieces of wood will be so perfectly cemented that boards thus joined will as readily break in any other part as at the junction. Glued boards will not set in a freezing temperature, the stiffening being occasioned by the evaporation of the superfluous matter of the glue, which is prevented by a considerable degree of cold.

The above is the usual kind of glue, and of which the largest quantities are employed; but there are other kinds of glue used for particular purposes which it will be proper to speak of in this place. Of these, fish glue is the most important, which is made of the skins and mucilaginous parts of fish. These, being boiled, bear a near resemblance to that viscid matter found on the skin of cod-fish. When boiled to the consistence of a jelly it is spread on a leaf of paper and formed into cakes, in which state it is fit for use. Fish glue is much used in medicine and many other Arts; but this is better known under the name of isinglass and ichthyocolla. A strong glue may be prepared with isinglass and spirits of wine, by steeping the isinglass for twenty-four hours in spirits of wine or common brandy. When the menstruum has opened and mollified the isinglass, they must be gently boiled together and kept stirring till they appear well mixed, and until a drop of it allowed to cool will soon turn to a strong jelly; it is now to be strained through a clean linen cloth into a vessel to be kept close stopped. A gentle heat suffices to dissolve this glue into a transparent and almost colourless fluid, but very strong, so that pieces of wood glued together with it will separate as easily any where as in the parts joined.

A strong compound glue may be made by infusing a mixture of common glue, in small pieces, with isinglass glue, in as much spirits of wine as will cover them, for about twenty-four hours; then melt the whole together, and as much powdered chalk is to be added as will make it an opaque white. By dissolving gum sandarac and mastic, of each two ounces, in a pint of spirits of wine, a strong glue may be obtained which will resist moisture; an ounce of clear turpentine must be added to the above mixture, equal parts of isinglass and parchment glue, pounded into small pieces; the solution of the gum is to be poured upon them, and the mixture melted in a covered vessel with a heat less than that of boiling water, then the glue, after being strained through a coarse linen cloth, is to be again placed over the fire, and an ounce more of powdered isinglass added to it.

Mechanical Processes.

Manufac-
tures.

Another strong glue that will resist water may be made by adding half a pound of common isinglass glue to two quarts of skimmed milk, and evaporating the mixture to a due consistence. A glue that will hold against fire and water may be made by mixing a handful of quicklime with four ounces of linseed oil, and boiling them to a good thickness, and spreading the mixture on tin plates in the shade; it will thus become extremely hard, but will easily be dissolved over a fire and be fit for use.

Sealing-wax.

Sealing-
wax.

(1142.) This well-known substance is a composition of gum lac melted and prepared with resins, and coloured with pigments of various hues, of which, however, the prevailing one is red. The hard red sealing-wax is made by mixing two parts of shell-lac, well powdered, and resin and vermilion, also reduced to a fine powder, of each one part; these are then melted together over a slow fire, and, when they appear thoroughly incorporated, formed into sticks in moulds ornamented or plain. Seed-lac may be substituted for the shell-lac, and instead of resin boiled Venice turpentine may be used. There is a coarser kind of hard sealing-wax, which may be made by mixing two parts of resin and of shell-lac, vermilion, and red lead, in the proportion of one part of vermilion to two of the red lead; the process of making this is like that of the former. The vermilion and shell-lac may both be omitted when cheapness is an object, but the wax thus made is of a very inferior kind. The best black, hard sealing-wax is prepared as above, except that the best ivory black is substituted for the vermilion, and in the coarser kind the common ivory black. Coloured sealing-waxes are prepared in other respects the same as the above, only altering the colouring matter, viz., for the green, instead of vermilion powdered verdigrise is employed; for a bright colour, distilled or crystals of verdigrise; for blue, powdered smalt, or for light blue, verditer or a mixture of both; for yellow substitute masticot, or for a bright colour turbith mineral instead of the vermilion. The hard purple wax is made like the red, only lessening the quantity of vermilion, and taking a larger or smaller proportion of smalt, according to the required shade of colour. The soft sealing-wax uncoloured is prepared by taking of bee's-wax one pound, turpentine three ounces, and of olive oil one ounce; they must be put in a proper vessel over the fire and allowed to boil for some time, when the wax will be in a proper state to form into rolls or cakes for use. To colour such soft wax, an ounce or more of any of the ingredients above mentioned must be stirred in while boiling till thoroughly incorporated with the wax. The hard sealing-wax is formed into sticks by rolling the mass on a copper plate or stone, with a rolling board lined with copper or block tin, into rolls of any required size. The polish or gloss is given to the sticks of wax by exposing them to a fire; for this purpose a furnace or stove is used resembling a pail, with bars at the bottom for holding the charcoal, and notched at the top of the sides for putting the wax over the fire; in this manner the sticks are conveniently turned about till the wax is so melted on the surface as to become smooth and shining. Hard sealing-wax may be formed into balls by putting a proper quantity on a plate, and, when made into a round form, it is to be rolled with the board till it becomes smooth. By pouring the soft wax into cold water it is easily formed

into rolls or cakes, and working it with both hands into any desired figure. These kinds of wax are sometimes perfumed; in which case to a pound of wax is added half an ounce of benjamin, one scruple of oil of rhodium, ten grains of musk, and of civet and ambergris each five grains, rubbing the oil with the other powdered ingredients, and, when the wax is in a fit state for working into sticks, the mixture must be sprinkled in and well stirred; or the same may be done by using one ounce of benjamin, one scruple and a half of oil of rhodium, and five grains of ambergris in the same manner.

Mechanical
Processes.

(1143.) *Wafer-making* for sealing letters are made by mixing fine flour with the white of eggs, isinglass, and a little yeast; this mixture is to be beaten into a paste; it is then thinned with gum water, and spread on even thin plates, dried in a stove, and cut for use. The different colours are given by tinging the paste with Brazil or vermilion for red; indigo or verditer, &c. for blue; saffron, turmeric, or gamboge for yellow, &c.

Wafers.

Starch-making.

(1144.) *Starch* is a substance employed in various processes in the Arts, and, although generally it is not made in quantities to require the application of large machinery, it is one which we think requires to be noticed in this place. Almost all kinds of seeds and the roots of most vegetables afford this substance in a greater or less degree; it is, however, obtained in greater abundance from wheat flour. This being moistened and made up into the form of dough or tough paste, and a gentle stream of water allowed to pass over or fall upon it, this will be found, when it leaves the paste, thick and turbid, which is occasioned by the starch or fecula which it extracts from the flour, and which subsides when the water is allowed to stand at rest. The substance thus obtained, when dried in the sun or by stove, is usually contracted into small masses of a long figure in the form of angular columns, which have a fine white colour, without smell and with very little taste; it is not soluble in cold water, but with boiling water it forms a thick paste, which, if allowed to cool, becomes semitransparent and gelatinous, and when dry is brittle, and somewhat resembling gum.

Starch,
nature of
described.

The process above described is too slow and expensive to be followed in manufacturing starch in large quantities. Here wheat, or such parts of it as are not used for food, is usually employed, such as the refuse wheat and bran; but when the finest starch is required, good grain must be used. This being well cleaned, and sometimes coarsely bruised, is put into wooden vessels full of water to ferment, and to assist the fermentation the vessels are exposed to the heat of the sun, and the water changed twice a-day during eight or twelve days, according to the season; the grain then bursts easily under the finger, and gives out a milky white liquor on being squeezed, when it is judged to be sufficiently softened and fermented. In this state the grains are taken out of the water in a sieve, and put into a canvass sack, the husks being separated and rubbed off by beating and rubbing the sack upon a plank; the sack is then put into a tub filled with cold water, and trodden or beaten till the water becomes milky and turbid from the starch which it takes up from the grain in this state. A scum swims upon the surface of the water; it must be carefully removed, and the water then run off

Mode of
manufac-
ture.

Manufac-
tures.

through a fine sieve into a settling vessel, where fresh water is poured upon the grain two or three times till it will not extract any more starch, or become coloured by the grain. The water in the settling vessels, being left at rest, precipitates the starch which it held suspended, and to get rid of the saccharine matter, which is also dissolved by the water, the vessels are exposed to the sun, which soon produces the acetous fermentation, and thus renders the starch more pure and white. During this process, the starch for sale in the shops receives its colour, which consists of smalt mixed with water and a small quantity of alum, which is thoroughly incorporated with the starch; but this starch is unfit for some other purposes. When the water becomes completely sour, it is poured gently off from the starch, which is washed several times afterwards with clean water, and at last is placed to drain upon linen cloths supported by hurdles, and the water drips through, leaving the starch upon the cloths, in which it is pressed or wrung to extract as much as possible of the water, and the remainder is evaporated by cutting the starch into pieces, which are laid up in airy places upon a floor of plaster, or of slightly burnt bricks, until it becomes completely dried from all moisture, partly by the effect of dry air and partly by the floor imbibing the moisture. In winter-time the heat of a stove must be employed to effect the drying; the pieces of dried starch are scraped to remove the outside crust, which makes inferior starch, and these pieces are broken into smaller pieces for sale. The grain which remains in the sack after the starch is extracted contains the husks and the glutinous part of the wheat, which are found very nutritious food for cattle.

French
method.

The French manufacturers, according to *Les Arts et Métiers*, pursue a more economical method, as they are enabled, by employing an acid water for the fermentation in the first instance, to use the most inferior wheat, and the bran or husks of wheat. This water they prepare by putting a pailful of warm water into a tub with about two pounds of leaven, such as bakers use to make their dough rise or ferment, the water stands two days and is then stirred up, and half a pailful of warm water added to it; then being left to settle till it is clear, it is poured off for use. To employ this water in the fermentation of the materials, a quantity of it is poured into a tub, and about as much fair water is poured upon it as will fill the tub half full. The remainder is then filled up with the materials, which are one half refuse wheat, and the other half bran. In this tub it continues to steep and ferment during ten days or less, according to the strength of the leaven water, and according to the disposition of the weather for fermentation. When the materials have been sufficiently steeped or fermented, an unctuous matter, which is the oil of the grain, will be seen swimming on the surface, having been thrown up by the fermentation; this being skimmed off, and the fermented grain taken out, is put into a fine hair sieve placed over a settling tub, when clear water is poured upon it and washed through the sieve into the tub, by which means the starch is carried through the sieve, with the water of which about six times the quantity of the grain is used. This water stands in the settling tub for a day, and becomes clear at top, when it is carefully laded out, leaving at the bottom a white sediment, which is the starch. The water thus taken off is called sure water; this is the proper leaven for the first steeping of the materials. The starch now ob-

VOL. VIII.

tained must be rendered marketable; for which purpose as much water is poured upon it as will enable it to be pounded and broken up with a shovel, and then the tub is filled up with clear water. Two days after this the water is laded out from the tub, and the starch appears at the bottom, but covered over with a dark-coloured and inferior kind of starch, which is taken off and employed for fattening hogs. The remainder of the sediment, which is good starch, is washed several times to remove all the inferior starch; and when this is done, about four inches of thick starch should be found at the bottom of each vessel, but the quantity varies according to the goodness of the meal or bran which has been used.

Mechanical
Processes.

It is evident that the refuse wheat when employed for making starch ought to afford more, the whole being used, than the bran or husks; but the starch so extracted is always of an inferior quality to that which is extracted from the bran of good wheat, particularly in the whiteness of its colour. In order to equalize the quality, the starch in the different vessels is mixed together in one, and there worked up with as much water as will dissolve the starch into a thin paste, which is put into a silk sieve and strained through with fresh water. This water is left to settle in a tub, and is afterwards poured off, but before it is so completely settled as to lose all its white colour; this renders the starch which is deposited still finer and whiter, and the starch which is deposited by the water so poured off is of a more common quality.

The starch thus purified is taken out of the bottom of the vessels and put into wicker baskets about eighteen inches long and ten deep, rounded at the corners, and lined with linen cloths which are not fastened to the baskets; the water drips from the starch through the cloths for a day, and the baskets are then carried up to apartments at the top of the house, where the floor is made of very clean white plaster, and the windows are thrown open to admit a current of air. Here the baskets are turned downwards upon the plaster floor, and the linen cloths not being fastened to the baskets follow the starch, and when taken off leave loaves or cakes, which are left to dry a little; these are then broken into smaller pieces, and left on the plaster floor till very dry; but if the weather be at all humid the starch is removed from the plaster floor and spread out upon shelves in an apartment which is warmed by a stove, and there it remains till perfectly dry. The pieces are afterwards scraped to remove the outside crust, which makes common starch, and the scraped pieces being again broken small, the starch is carried to the stove and spread out to a depth of three inches on hurdles covered with cloths. The starch must be turned over every morning and evening to prevent it from acquiring a greenish colour, which it would otherwise do.

(1145.) Potatoes are sometimes used for making starch by soaking them about an hour in water, and taking off their roots and fibres, then rubbing them quite clean with a strong brush, after which they are reduced to a pulp by grating them in water. This pulp is to be collected in a wooden vessel, and mixed up with a large quantity of clear water; at the same time another clean vessel must be provided, and a hair sieve, not too fine, must be supported over it. The pulp and water are thrown into the sieve, and the flour or starch is carried through with the water; fresh water must then be poured on till it runs through quite clear. The refuse pulp which remains in the sieve, being boiled in water,

Potato
starch.

Manufac-
tures.

makes an excellent food for animals; it is near seven-eighths of all the potatoes employed.

The liquor which has passed through the sieve is turbid, and of a darkish colour, from the extractive matter which is dissolved in it; but when it is allowed to rest for five or six hours all this matter deposits or settles to the bottom, and the liquor which remains is poured off as useless, and a large quantity of fresh water is thrown upon the flour and stirred up; it is then left to settle for a day, and, the water being poured off, the flour will be found to have again settled in a whiter state. But, to improve it, another quantity of water is poured on and mixed up with it, in which state it is passed through a fine silk sieve to arrest any small quantity of the pulp which may have escaped the first hair sieve. The whole must afterwards be suffered to stand quiet till the flour is entirely settled, and the water above become perfectly clear; but if the water has any sensible colour or taste, the flour must be washed again with fresh water, for it is absolutely necessary that none of the extractive matter be suffered to remain with it. The flour, when thus obtained pure and drained from the water, may be taken out of the tub with a wooden shovel, and placed upon wicker frames covered with paper, to be dried in some situation properly defended from dust.

Starch-mill. (1146.) When this manufacture is carried on in a large way, some kind of mill must be used to reduce the potatoes to a pulp, as the grating of them by hand is too tedious an operation. A mill invented by M. Baumé is very complete for this purpose. In its general structure it resembles a large coffee-mill. The grater consists of a cone of iron plate, about seven inches in diameter and eight inches in height, the exterior surface of which is made toothed like a rasp by piercing holes through the plate from the inside. This cone is fixed upon a vertical axle with a handle at the top to turn it by, and is mounted on the pivots of the axle within a hollow cylinder of plate iron, toothed withinside like the outside of the cone, the smallest end of the interior cone being uppermost, and the lower or larger end being as large as the interior diameter of the hollow cylinder. A conical hopper is fixed to the hollow cylinder round the top of it, into which the potatoes are thrown, and falling down into the space between the outside of the cone and the inside of the hollow cylinder, they are thus ground and reduced to a pulp when the interior cone is turned round by its handle, and as the lower part of the cone is fitted close to the interior diameter of the cylinder, the potatoes must be ground to a fine pulp before they can pass through between the two. The machine when at work is placed in a tub filled with water, and as fast as the grinding proceeds the pulp mixes regularly with the water ready for the process before described.

Mr. Whately's starch-mill.

A mill for the same purpose, on a different plan, has been proposed by Mr. Whately. This is a cylinder with its axis horizontal and turned by a handle at one end with a fly-wheel to regulate the motion; a hopper is placed over the cylinder into which the potatoes are thrown, and they are grated by resting upon the cylinder as it revolves round. There is also a horizontal box opposite to the cylinder into which the potatoes are received from the hopper through a sliding door; and a movable end, which is fitted to the box, is pressed forwards towards the cylinder by a lever and weight, so as to force the potatoes contained in the box against the cylinder, which being kept in constant motion grates

away the potatoes into a pulp with great rapidity, which falls into a box beneath.

In the year 1796, Lord William Murray obtained a Patent for manufacturing starch from horse-chestnuts. The method was to take the horse-chestnuts out of the outward green prickly husk, and either by hand with a knife, or tool, or otherwise with a mill adapted for the purpose, the brown rind was carefully removed, leaving the chestnuts perfectly white and without the smallest speck. In this state the nuts were rasped or ground to a pulp with water, and the pulp washed with water through a coarse horse-hair sieve, and twice afterwards through finer sieves, with a constant addition of clear cold water, till all the starch was washed clean from the pulp which remained in the sieve, and the water being settled deposited the starch, which was afterwards repeatedly washed, purified, and dried, in the same manner as the potato starch before described.

The sour, nauseous, milky liquor obtained in the process of starch-making appears, upon analysis, to contain acetous acid, ammonia, alcohol, gluten, and phosphate of lime. The office of the acid is to dissolve the gluten and phosphate of lime, and thus to separate them from the starch.

Another Patent has been obtained by Mr. Hill, the object of which is to deprive the starch of all its colouring matter, and to render it perfectly white by the action of the oxymuriatic acid. When the starch is ready for boxing, it is reduced with water to the consistence of cream. The oxymuriate of lime is then added to it and the whole continually agitated. A large quantity of water is next added, the mixture is well stirred, and the starch allowed to subside. The water is then drawn off, and dilute sulphuric acid poured upon the starch, and the whole agitated for some time. The starch is finally washed with repeated quantities of clear water, till all smell is removed from it.

Starch is used with smalt or stone blue to stiffen and clear linen; the powder of it is also used to whiten and powder the hair: the dyers also use it to dispose their stuff to take colours the better, and likewise for various other purposes.

The Amount of Duty paid on Starch manufactured in this Country from 1820 to 1831, inclusive.

Years.	lbs.	£.
1820	4,605,251	50,013
1821	4,658,141	54,198
1822	5,435,160	75,803
1823	5,739,894	70,680
1824	5,517,409	67,549
1825	6,621,782	74,554
1826	6,188,778	70,050
1827	4,357,969	85,239
1828	7,765,273	87,348
1829	6,367,207	66,699
1830	7,872,823	84,833
1831	7,557,336	78,805

Staining Paper.

(1147.) This is an important branch of the decorative Arts in this Country, and brings in some considerable amount in the form of revenue, every piece of paper thus employed being subject to a certain duty. There are three different kinds of paper, or rather three different ways of staining paper for hangings, viz. first, by printing

Mechanical
Processes.

Lord W.
Murray's
Patent.

Manufac-
tures.

Block-
staining.

on the colours; secondly, by what is called stencilling; and thirdly, by laying on the colours by pencil and brush; to which we may also add flock paper.

First method, with blocks.—When the colours are laid on by printing, the impression is made by wooden prints, which are cut in such a manner that the figure to be shown projects from the surface, by cutting away all other parts. This being charged with the colours tempered with their proper vehicle, by letting the print gently down on a block, on which the colour is previously spread, conveys it from thence to the ground of the paper, on which it is made to fall more forcibly by means of its weight, and the effort of the arm of the person who uses the print. The manner of performing this process may be more clearly understood by the following description. The paper, being properly prepared by a ground of whiting, colour, or varnish, is laid on a proper block, on which a piece of leather is stretched, and the colour, mixed with its proper vehicle, is spread on another piece of leather or oilcloth, laid on a flat block somewhat larger than the print, which is done by a boy or man who attends for that purpose, who, having the colour by him in a pot, spreads it with a brush on the block betwixt every stroke and impression the printer makes. The print is previously cut in such manner, correspondently to the design of the painting, that there shall be a projection on the surface answering to every part where that colour intended to be conveyed by this print is necessary; the workman takes the print and drops it gently on the block just charged with colour; from whence he again immediately raises it in the most perpendicular direction, and lets it fall with all his force on the paper, taking care to keep it perfectly even. This being done, the sheet printed is taken directly off the block and hung up to dry; and, another being put in its place, the same operation is repeated till the whole quantity is printed. It is easy to conclude that there must be as many separate prints as there are colours to be printed, and that they are to be used successively in the same manner as at first. But where there are more than one, great care must be taken after the first to let the print fall exactly in the same part of the paper as that which went before, otherwise the figure of the design would be brought into irregularity and confusion. In common paper of low price, it is usual, therefore, to print only the outlines, and lay on the rest of the colours by stencilling, which both saves the expense of cutting more prints, and can be practised by common workmen, not requiring the great care and dexterity necessary to the using of prints.

Printing by
the stencil.

(1148.) *Second method, by the stencil.*—This is effected as follows: the figure, with all the parts of any particular colour introduced into any proposed design, is cut out in a piece of oilcloth; this is called a stencil, and, being laid flat on the piece of paper to be stained, spread on a table or floor, is rubbed over with colour, properly mixed and tempered, by means of a large brush. The colour, passing over the whole, is of course spread on the paper where the cloth is cut away, and produces the same effect as in the block-staining above described. This practice, however, requires great care, particularly where there are small spots in the pattern, and where there are small continued lines running one into another; for in these cases it is difficult to preserve the connection or continuity of the parts of the oilcloth, or to keep the corners close down to the paper; for such patterns, therefore, blocks are preferable. Stencilling is, indeed,

a coarser and cheaper process, if done in an ordinary way; but to bring out as good effect as the block-staining requires so much care and skill, that the advantage of cheapness is lost; it is, therefore, we believe, seldom attempted except on bare walls, by which something like the effect of paper is produced, without incurring the expense of that material.

(1149.) *Third method, by the pencil.*—This being a slow process, and requiring the hand of an artist, is of course expensive, and is only had recourse to for the nicer sort of work; it is performed in the same manner as other paintings in water or varnish. In some cases it is employed only to fill the outlines already prepared by printing, where the price of the colour or the nicety of the design renders the block less proper for completing the process; sometimes it is used for forming or delineating some parts of the proposed figures, where a spirit of freedom and variety is required beyond what can be effected with the block.

In common pencil work, the method is first to stencil all parts of the colour in the design, and to give an outline to the whole at last with brown or black; but where there is any running parts, such as scrolls or stems or stalks of creeping plants or flowers, which are to be printed in any other colour than brown or black, a print must be used for them.

In the finer paper, where several colours are laid on with the prints, the principal colour is begun with, and the rest taken successively, the print for the outline being laid on last. In other cases, where the pencil is to be used, the outline is nevertheless to be made before the colours are laid on by the pencil, because, without this precaution, the figures would be likely to deviate too much from each other both in outline and position.

In paper printed with designs in chiaroscuro, such as the imitation of stucco-work and bas relievos, the order of printing must be to lay on the ground colour first, then the shades, and lastly the lights, and the same rule of succession must be observed where the colours are pencilled.

(1150.) *Flock paper.*—This is comparatively a late invention. The flock, which gives a great body and strength to paper thus coloured, is made from chopped cloth. The paper designed for this process is generally first prepared with a varnish ground of the proper colour, and it is not uncommon to print some small running figure in colours on the ground before the flock is laid on, which may be done with any pigment of the colour desired, tempered with varnish and laid on by a print or block cut for the purpose, the flock itself being afterwards laid on by a print or stencil. But as the latter can execute nothing but detached parts, and, consequently, is unfit for all designs where running work, scrolls, or other more complicated ornaments are introduced, it is extremely confined with respect to the nature of the designs for which it can be employed, and the print is therefore most generally preferred. The method of laying on the flock by means of a print is by having a print which is already cut in such a manner that the part of the design which is intended for the flock may project beyond the rest of the surface; the varnish is put on a block covered with leather or oilcloth, and the print is then used to lay the varnish on all the parts where the flock is to be fixed. The sheet, thus prepared by the varnished impression, is now to be removed to another block or table, and to be strewed over with flock, which is afterwards to be gently compressed by

Mechanical
Processes.

With the
pencil.

Flock
paper.

Manufac-
tures.

a board or some other flat body, to make the varnish take the better hold of it. Then the sheet is to be hung on a frame till the varnish is perfectly dry; at which time the superfluous part of the flock is to be brushed off by a soft camel-hair brush, and the proper flock will be found to adhere in a very strong manner. When the stencil is used, the same method is to be pursued, the varnish for holding the flock being laid on by that instead of a print, and the flock afterwards strewed upon it, as in the other case. The common manner of using the flock is by cutting woollen rags or pieces of cloth with the hand, by means of a large bill or chopping knife. But it is much more easily and better done by a machine, which may be worked by a horse-mill; at the same time such mill is employed for any other purpose, as grinding colours, &c. In such case, the construction of that part of the machine, which is made for the cutting the flock, is to take a box made for containing the rags or cloth to be cut, which is open at the top, and of such size as may best suit the quantity of rags that the force employed can cut. A blade is also to be made, the length of which is to be equal to the breadth of the box, and it should be strong, and must be charged with as great a weight as the force employed can be made to raise with a quick motion. The box, being filled with the rags or cloth to be cut, is placed under the blade, and made to move by hitches, after the stroke of the blade is given, just so far as where it is proper the blade should again cut the cloth or rags; while, at the same time, the blade is lifted up and let fall on the cloth, which it cuts through, till by successive strokes, and the progressive motion of the box under it, the whole quantity of cloth or rags in the box has been cut. The box must then be turned, so that one of the sides may become the front, and the operation must be repeated; by which means the cloth or rags, having been cut both ways, will be reduced to the state in which the matter is called flock, and fit to be employed for the purpose of paper-hanging. The work necessary for conveying from the principal mover in the mill the motion for thrusting forward the box and raising the blade may be easily supplied by any ingenious wheelwright, and need not, therefore, be particularly described here.

There is a kind of counterfeit flock paper which, when well managed, has very much the same effect to the eye as the real, though done with less expense. The manner of making this kind is by laying a ground of varnish on the paper, and having afterwards printed the design of the flock in varnish in the same manner as above; instead of the flock, some pigment or dry colour, of the same hue with the flock required by the design, but somewhat of a darker shade, being well powdered, is strewed upon the printed varnish and produces nearly the same appearance. *Handmaid of the Arts*, vol. ii. p. 458, &c.

Colours
used by
paper-stain-
ers.

The colours proper to be used for painting paper-hangings are all those that can be used in water and varnish; but for common designs done with water only the following are most proper: for red, lake vermillion, rose pink, and red ochre; for blue, Prussian blue, verditer, and indigo; for yellow, the yellow-berry wash, Dutch pink, and yellow ochre; for green, verdigrise, or a mixture of the blue colours with the yellow colours, particularly with the yellow-berry wash; for orange, vermillion or red lead, with Dutch pink; for purple, a wash made of logwood, or a mixture of the lake or rose

pink with deep-coloured Prussian blue, or with indigo; for black, ivory-black, and in some nicer cases lamp-black; for white, whiting; and for the heightnings, white lead; where great brightness is required, the lake should be used for the crimson red, and Prussian blue for the blue; but, for many purposes, rose pink used alone for the crimson red, and indigo mixed with whiting for the blue, will answer the purpose with much less expense. The lake, rose pink, Prussian blue, and Dutch pink, intended for this use, should be procured in a moist state. The colours used in varnish may be the same as those used in water; but for this purpose, those just mentioned should be obtained dry. As for the vehicles of the colours, when water is used, it must be inspissated with size and gum arabic or Senegal. When burnish is used, it must be formed of oil of turpentine, and the resins and gums which will dissolve in that menstruum. With respect to the grounds for paper-hanging, those that are laid in water are made by mixing whiting with the size above mentioned, and laying it on the paper with a proper brush in the most even manner. Nothing is more necessary when the ground is to be left white; and the paper being hung on a proper frame till it be dry is fit to be painted. When coloured grounds are wanted, the same method must be pursued, and the ground of whiting first laid, except that in paler colours a second coating may sometimes be spared by mixing some strong colour with the whiting. But where a greater force of colour is wanted, the pigment or colouring substance must be tempered with the proper vehicle, and then spread over the white coat. The varnish grounds are made much in the same manner, by mixing the proper colour with the varnish and spreading it on the paper.

(1151.) *Duty on stained paper.*—The stained-paper duty was imposed by the original Paper-Duties Act, (10 Anne, c. 18,) and is distinguished by its being a second charge upon an article already highly taxed in its plain or simple state. "Printed goods and stained paper" appear to have been officially classed together by the Board of Excise; and the Commissioners of Excise Inquiry observe, that it is remarkable the latter duty was not repealed at the same time with the former, to which it was much more analogous than to the paper duty.

The present duty on stained paper is 1½d. per square yard, averaging about 1s. per pound in addition to the 3d. per pound levied on the paper in its plain state. A drawback of the whole duty of 1½d. is allowed on exportation.

The amounts of stained paper charged with duty, and of revenue received therefrom, in the year ended 5th January, 1835, are as follows:

	Yards.	Revenue.
England	8,071,094	£58,851 14 6
Scotland	59,782	435 18 2
Ireland	618,268	4,508 4 1
	8,749,144	£63,795 16 9

There are 108 paper-stainers in England, two in Scotland, and forty-six in Ireland, each of whom is charged with a license duty of £4.

From the Excise regulations it appears that the stained-paper duty is charged on all paper prepared for use before it is stained; and that if a sheet therefore becomes spoiled or unsaleable in the staining, the paper-stainer must bear the loss.

The price of stained paper is stated to be 2s. 6d. per

Mechanical
Processes.

Manufac-
tures.

piece; the two duties amount to 1s. 3d., so that we have at once 100 per cent. of duty, in addition to incidental expenses, and to the losses of the nature above described.

The operation of this disproportionately high duty is very severely felt, particularly in the inferior papers, with regard to which Sir James Williams states, that "for 100 pieces of high-priced paper they sell 1000 of the low-priced." In such a state of things it is almost needless to add that evasion of duty takes place to a great extent, more especially in Ireland, where out of forty-six paper-stainers fourteen appear, from the Excise return for 1832, to have paid duty under £10, forty-three under £100, and three only paid duty above that amount. It is asserted that Irish stained paper is imported into England, and sells for one-third less than English paper, so that the evasion of duty in Ireland is not only injurious to the revenue, but prejudicial to the interests of the manufacturers of the United Kingdom.

Varnish Manufacture.

Various
uses of var-
nish.

(1152.) In the present advanced state of society in this Country, the decorations and elegances of life employ a great number of workmen in various Arts which were formerly almost unknown; and amongst these the manufacture of varnish may be included. The common bare walls of our ancient palaces were first hung with tapestry, then in less magnificent buildings stained paper, and now very commonly varnished painted walls are considered the most elegant finish to the architectural decoration of the finer rooms. The varnish for coach bodies used in this Country is also very considerable, as well as for various other decorations; so that the making of varnish, which was formerly merely the business of the artist who employed it, is now a distinct trade, and is carried on in many places on a considerable scale.

Apparatus
used in the
manufac-
ture.

Apparatus for varnish-makers.—In the *Transactions of the Society of Arts, &c*, vol. xlix., Mr. Neil, of King's Cross, Battle Bridge, has given a very particular description of the buildings and apparatus employed in this manufacture, and from this article we shall select such description as is consistent with our general plan.

The apparatuses employed are, 1. what is called the set pot, which is employed in boiling oil, gold size, japan, and Brunswick black; this is an iron vessel of the form of a common copper, about two feet deep, and two feet diameter, set in brickwork, having a spiral flue round it for about half its depth; 2. the boiling furnace; 3. the gum furnace; 4. the gum pot; 5. the boiling pot, copper ladles, sieves, &c. We do not consider it essential for our purpose to enter into a minute description of those parts which do not differ essentially from the usual form of such apparatus used in other similar processes, but, at the same time, any person wishing to carry forward such a process on a large scale may advantageously consult the Work to which we have referred.

Processes
described.

(1153.) *Process of varnish-making.*—As the least dust is exceedingly injurious to the varnish, it is important at the beginning of the operation that the making house be swept very clean. A quantity of oil, as for example eight gallons, is now placed in the boiling pot to be boiled, and in the gum pot is put first eight pounds of gum, when, the fire having been previously lighted, it will in a short time begin to give out steam and acid;

this must now be stirred and divided by the workman, and in about twenty minutes it will be found clear, resembling oil. During this time the oil is also so far heated as to simmer rather smartly; the boiling pot with the oil is now lifted off the fire, carried outside the building, and about one-sixth of the heated oil is poured into a copper vessel and emptied into the gum pot; the boiling is then continued until the oil and gum become concentrated and the mixture looks clear. Another sixth part of the oil is now added, and then again a third. These last operations are performed out of the first building, the gum pot having been removed for the purpose; there still remains about half the oil in the oil pot, and to this half the mixture of oil and gum in the gum pot is added; half a gallon of turpentine is then thrown into the empty gum pot, and with this and a *swish* it is well washed, and the contents emptied into a proper vessel; the pot is then wiped dry, placed again over its furnace with eight pounds more gum, which is proceeded with exactly as before, and then again with eight pounds more gum, when there will be in the boiling pot eight gallons of oil and twenty-four pounds of gum well incorporated; under this is kept up a brisk strong fire, till a scum or froth rises and covers the surface. It is now removed from the fire and taken to the place where the mixing was made, and well stirred, introducing the driers, and if the scum go down it is placed again over the fire; this process must be continued till the driers are all well incorporated; it is then mixed, when of a proper temperature, with about fifteen gallons of turpentine. In this state it is fit for use.

Mechanical
Processes.

(1154.) *Different Description of Materials for forming Varnishes.*

Gums copal.—Gums copal are of three different sorts and qualities; the best is brought from Sierra Leone; when imported, it is about the size of small potatoes, and is covered with a rough coat of dust or clay-like substance. It is most commonly bought in that state by varnish-makers, gum dealers, and druggists, who scrape it, that is, they generally have women who scrape it with sharp penknives or razors; it is indeed rather pared than cut quite free from dust; it is afterwards picked by hand into three different qualities. All the finest and palest is put by itself; this is called body gum; the next best is called carriage gum; from the remainder all pieces of wood, stones, &c., are taken away, and the remnant is made to serve for gold size or japan black.

Description
of materials
for varnish.

The second sort of gum copal, imported from South America, is, in appearance, somewhat like the African but much larger, and to those who are not good judges appears far the best, although in reality not worth one-third the value of the African; for after all the labour of scraping, picking, &c., it is in general so full of acid and sap, that not above two-thirds of it is fusible, and in many instances not more than one-third, and some whole casks are imported not worth any thing.

The third sort of gum copal is never imported by itself, but is found mixed among the gum animi; it is very large, pale, hard, and transparent, fuses and fixes well, and makes excellent varnish.

Gum animi is imported from the East Indies. It was formerly sold at the Company's sales in lots of two chests, each weighing from three to five hundred-weight, the sizes varying very much, as well as the quality.

Manufac-
tures.

The chests which contain the palest and largest gum always sell for the highest price, particularly those chests which are imported ready scraped; but there are great quantities imported which come over unscraped, being termed pickled, that is, cleaned from its dust by laying for several days in a very strong alkali well washed with a broom in water. This sort is not so good as that which is scraped with a knife; it is generally sold for one-third less than the former; but, in pickling and sorting animi, care must be taken to pick out all the fine, large, and transparent pieces: these are called body gum; the remainder is then picked and sorted.

Amber.—There are two kinds of amber, each of various qualities; the best is imported from Prussia and Poland; it is found in mines and rivers; it is very thin, solid, pale, hard, and transparent. Beads and other curiosities are made from this kind; it forms the most solid, hard, and durable varnish that can be made, either by employing it by itself, or as a component part with other gum. The other sort of amber is called sea-amber; it comes from many places abroad; its appearance is much darker than the first, and is about the size of coffee beans, more difficult to fuse, has less fluidity, affords more salt, gas, and acid during its fusion, and leaves a considerable quantity of impure earthy matter at the bottom of the pot on fusion, whereas the best kind will completely dissolve like oil.

Gum sandarach is so well known that no description is necessary.

Gum mastic may be procured at any druggist's shop, and is likewise well known. When very fine mastic varnish is required for valuable paintings, the mastic is put out upon a tea-tray or mahogany table, and every fine and clean piece picked out, until all the inferior, small, yellow, and dirty pieces are left; the fine is reserved for picture varnish, and the inferior for common mastic varnish.

Gum cat's eye is a large, pale, transparent gum, but little known; it is quite resinous and pulverulent between the teeth; it resembles gum sandarach; it is very pale, may be dissolved in hot turpentine, and is but little used except in making a varnish for paper-hanging, and adulterating common cheap mastic varnish; it is indeed very little better than pale rosin.

These are the principal gums required for making varnish; all others being in such small quantities, their description is unnecessary.

After having procured the necessary gums and sorted them, they are to be reduced to proper sizes for the gum pot, viz., to about the size of hazle-nuts, the larger pieces being broken by a proper hammer upon a thick sheet or plate of lead, in the course of which operation all black, dirty, or watery pieces are taken away to be mixed with other sorts of the same kind for common purposes.

Linseed oil is of peculiar consequence to the varnish-makers, as upon its quality in a great degree depends the beauty and durability of the varnish. Oil expressed from green, unripe seed always abounds with watery, pulpy, acidulous particles; the quality of oil may easily be determined by filling a phial with it, and holding it up to the light; if bad, it will appear opaque, turbid, and thick, its taste will be acid and bitter, and its smell rancid and strong; but the oil from fine, full-grown, ripe seed, when put to the same test, will appear limpid, pale, and brilliant, the taste will be mellow and

sweet, and it will have but little smell; it is specifically lighter than impure oil, and when clarified dries quickly and firmly; it does not materially change the colour of the varnish when made, but appears limpid and brilliant.

Essential oil, or spirits of turpentine, used for mixing varnish, ought to be chosen as pure, strong, and free from acid as possible. Turpentine which is drawn from green trees abounds with a pyroligneous acid which rises and comes over with the spirit in distillation; it is strong and bitter to the taste, and appears milky, particularly towards the bottom, after standing to settle.

Sugar of lead, when sought for the purpose of adding to varnish as a drier, ought to be that which has been made from white lead, instead of that from litharge, the former being the finest, and in its particles more pure and transparent. All sugar of lead contains about 14.2 per cent. of the water of crystallization, so that to use it in that state is very injurious to the varnish, as the water prevents that complete union of the particles of gum, oil, and lead, which ought to combine instantly and form a whole; therefore it is necessary to bruise the sugar of lead into powder, and lay it upon cartridge paper over a warm drying stove, where it should be frequently turned and moved about to prevent its running into a mass, until it gradually dries; it will then feel quite fine and soft, resembling hair powder; it should then be sifted through a forty-mesh sieve, which process renders it fit for the driers. It must be kept closed up in a dry stone jar until used, otherwise it will absorb moisture from the air.

White copperas, or sulphate of zinc.—The foreign article so called is chiefly imported from Germany; it is generally used as a drier for varnishes; in its undried state it is more objectionable than the sugar of lead, because it both discolours the varnish and injures the oil by affecting both its elasticity and durability. Another objection to its use in this state is that it requires the varnish to be kept for many months to settle, and if the varnish is not made very thin it does not get clear of the zinc at the bottom of the cistern; but when well dried it is the strongest and most effective drier, because it is entirely free from its watery particles.

Litharge is chosen as free from extraneous earthy matter as possible; that from the richest and softest lead is the best; this is called wind blow; it is in large broad flakes, appears very bright, and feels soft between the finger and thumb when rubbed; whereas the bad quality is known by an opaque, dull, or earthy appearance, and feels hard and gritty to the touch, and is very full of extraneous matter.

Red lead, like litharge, should be as free from earthy and extraneous matter as possible; when good, it will be found to be a strong and efficient drier.

Asphaltum.—There are many kinds of this substance, but the best is from Egypt; it is black, glossy, and heavy, and when rubbed upon a hot poker readily melts; it emits a very strong, disagreeable smell, like that of garlic or assafoetida, and cannot be dissolved in oil, water, or turpentine.

The next best quality is from Naples, which resembles the other in its appearance, but it is much more free from dirt, and may be dissolved in oil. There is a kind made in England which approaches in quality the best French, Naples, or German; this is the residuum

Mechanical
Processes.

Manufactures.

left from the burning of rosin, pitch, or linseed oil, which the makers of lamp-black burn for the purpose of condensing.

(1155.) *Composition of different varnishes.*—Eight pounds of the best African gum copal is to be fused; when completely in a fluid state two gallons of hot oil (old measure) are put to it; it is then to boil fifteen minutes; three gallons of turpentine taken from the top of a cistern is then to be added; but when the varnish is strained, if it is found too thick, more heated turpentine must be mixed with it.

Composition of different varnishes.

Artists' virgin copal.—The most transparent pieces must be chosen from a good sample of African gum copal; they are to be broken very small and dried before a gentle fire; after they become cool they are to be pounded into a coarse powder; then broken bottles or flint glass is to be boiled in soft water and soda, in order to cleanse it thoroughly, which is likewise to be pounded; the glass is to be dried in an oven; two pounds of it is now to be well mixed with three pounds of the pounded copal, and to be put into the gum pot to fuse; the glass will prevent the gum from adhering together, so that but little fire is required. When it is in a sufficient fluid state three quarts of clarified oil, very hot, should be poured to it; it must then be allowed to boil some time; five quarts of old turpentine is to be put in, and then to be immediately strained; it must be exposed to the air and light, but kept both from the sun and wet until of sufficient age for use.

Cabinet varnish.—Seven pounds of fine African gum copal is to be fused and added to half a gallon of pale clarified oil; in three or four minutes it is to be taken out of doors, then three gallons of oil mixed with it; it is then rendered fit for use.

Best body copal varnish for coachmakers, &c.—Two gallons of clarified oil is to be added to eight pounds of fine African gum copal fused; it must be boiled very slowly for four or five hours until quite stringy; three gallons and a half of turpentine are to be mixed with it; it is then to be strained and poured into a cistern. Varnishes made entirely from African copal possess more fluidity, pliability, and softness than those made from animi; the former keep the colour better, but the latter become darker after they are applied. Genuine copal varnish wears well; it never cracks, but, since it takes a long time to dry, coachmakers add to two pots of it

8 pounds of fine pale gum animi,
2 gallons of clarified oil,
3½ gallons of turpentine.

To be boiled four hours. This, after it is strained, is put hot into the two pots of varnish and well mixed together; this is done to cause the whole to dry quick and enable it to take a polish sooner.

Common Body Varnish for Coachmakers.

8 pounds of best African copal,
3 gallons of clarified oil,
3½ gallons of turpentine.

Boil four hours, or until stringy. When mixed, it will produce about five gallons and a half.

8 pounds of the best gum animi,
2 gallons of clarified oil,
3½ gallons of turpentine.

Boil as usual. To be mixed and strained hot, and put into the former pot of African gum varnish. Two pots of animi varnish is to be put to one of copal; this

mixture will dry quicker and harder than the best body copal, but will not wear so long. Mechanical Processes.

Quick drying Body Copal Varnish for Coaches.

8 pounds of the best African copal,
2 gallons of clarified oil,
¼ pound of dried sugar of lead,
3½ gallons of turpentine

Boiled till stringy, and mixed and strained.

8 pounds of fine gum animi,
2 gallons of clarified oil,
¼ pound of white copperas,
3½ gallons of turpentine.

Boil as before. Mixed and strained while hot in the first-mentioned pot. The mixture of these two ingredients will dry in six hours in winter and four in summer; it is principally used for varnishing old work on dark colours, &c.

Best Pale Carriage Varnish.

8 pounds second sorted African copal,
2½ gallons of clarified oil.

Boiled till very stringy.

¼ pound of dried copperas,
¼ pound of litharge,
5½ gallons of turpentine.

Strained, &c.

8 pounds of second sorted gum animi,
2 gallons of clarified oil,
¼ pound of dried sugar of lead,
¼ pound of litharge,
5½ gallons of turpentine.

To be mixed to the first while hot. This varnish requires the same time to dry as the last mentioned; it is used for all the purposes of coachmakers, house painters, &c.; its drying quality and strong gloss makes it very useful for general purposes.

Second Carriage Varnish.

8 pounds of second sort of gum animi,
2½ gallons of fine clarified oil,
5½ gallons of turpentine,
¼ pound of litharge,
¼ pound of dried sugar of lead,
¼ pound of dried copperas.

Boiled and mixed as before. When three runs are poured into the boiling pot, and the regular proportions added and well boiled, it will dry in half the time of the former varnishes; it is principally used for dark work.

Wainscot Varnish.

8 pounds of second sorted gum animi,
3 gallons of clarified oil,
¼ pound of litharge,
¼ pound of dried copperas,
¼ pound of dried sugar of lead,
5½ gallons of turpentine.

To be boiled until it becomes very stringy, and then mixed and strained. This varnish is likewise used for the same purposes as the above, and dries in the same time. Mahogany varnish is either made with the same proportions, or with a small portion of gold size.

Manufac-
tures.

Black
japan.

Black Japan.

This is made by putting into a set pot forty-eight pounds of Naples or any other of the foreign asphaltums, (except the Egyptian,) and as soon as it is melted pour in ten gallons of raw linseed oil. Keep a moderate fire, and fuse eight pounds of dark gum animi in the gum pot mixed with two gallons of hot oil and pour it into the set pot. Afterwards fuse ten pounds of dark or sea amber in a ten-gallon iron pot, keep stirring it while fusing, and whenever it appears to be over heated and rising too much, lift it from the fire for a few minutes. When it appears completely fused, pour in two gallons of hot oil, and empty it into the set pot; continue boiling it for three hours longer, and during that time introduce the proper quantity of driers, leave it to cool, and afterwards mix it with turpentine.

Water-proof Cloth.

Making
water-proof
cloth.

(1156.) Various attempts have been made to render cloth water-proof, and these have been attended with more or less success; but that which has supplanted nearly all others is a patented invention of Mr. Mackintosh, dated 1824, "for rendering fabrics of hemp, flax, cotton, wool, silk, and various other substances impervious to water." This is effected by the employment of a thick elastic varnish, made by dissolving caoutchouc in a small quantity of coal oil. The proportion of coal oil required to dissolve a given quantity of caoutchouc will vary according to its peculiar quality, as well as that of the resin; but the average quantity required will be about a quarter of a pint of the oil to a pound of resin. To facilitate the solution, the caoutchouc is to be cut into as thin shreds as possible, and the heat of a steam bath applied; when the solution is completed it is to be strained from the residuum.

To apply the varnish thus prepared, the cloth is to be stretched upon frames, and brushed over with it, and the varnished surfaces of two pieces of cloth, while in a sticky yet tolerably hard state, are laid one upon the other and passed between rollers subjected to pressure, which firmly and inseparably unites them. A flexible and thoroughly water-proof material is thus obtained applicable to a variety of useful purposes, without the inconvenient and unpleasant varnished sticky surface so common in other water-proof coverings.

This useful invention has found applications in various cases, but more particularly for large capes, cloaks, and for great coats, the former principally for walking in, the latter for riding, as they are found when close too warm for the former. This sort of cloth is also used for air cushions and beds, for water-hose and other purposes. A very ingenious application of this cloth was also made in some of our recent Voyages of Discovery, in which it was found necessary to have boats constructed very light for the convenience of taking them over land. In this instance the boat is made of wicker-work, with a casing of water-proof cloth; and by such boats very considerable rivers and pieces of water have been crossed. Another application was made of this substance by Mr. John Cow, of his Majesty's Dockyard, Woolwich, who contrived to form bandages of it for broken limbs. The usual bandages give frequently great pain when any swelling takes place, and they have sometimes to be relieved to the danger of displacing the bone; but by making the bandage of this material, and providing it with a pipe and stop-cock, the bandage, at first but slightly put on, may be blown up to any degree of pressure required, when, the stop-cock being turned, it will remain so; but on any occasion such as is spoken of above, the cock may be opened and the bandage slackened, and the pressure again restored without in any way disturbing the bandage.

 Epsom salts, manufacture of, 619.
 Escapements of clocks, 897.
 — of watches, 907.
 Experiments on cements, lime, &c., 470.
 — on the elastic power of steam by order of the French Government, 135.
 — on the Liverpool and Manchester railway, 305.
 Explosions in coal mines, 239.
 Faraday's experiments on glass-making, 700.
 Fast and loose pulley, 50.
 Feeder, self-acting, for steam-engine furnaces, 186, 189.
 Files, engine for cutting, 232.
 Fire-engine, history of, 362.
 — escape by Davies, 365.
 Fishing-net manufacture, 1050.
 Flattening-mill, 934.
 Flax manufacture, 997.
 Flint glass, manufacture of, 693.
 — pan, in pottery, 650.
 Flock paper, 1150.
 Floor, temperature of a malting, 1119.
 Fly for regulating motion, 65.
 Fly-wheel and governor, 66.
 — theory of, 67.
 — construction of, 40.
 Forces, retarding, friction, 13.
 Forgery, means of preventing, 1092.
 Founding and foundry, 920.
 Framing of mill-work, 62.
 Friction, amount of, by different writers, 13.
 — Coulomb's theory of, 14.
 — Vince's experiments, 15.
 — Rennie's experiments and tables, 16.
 — of machines, 23.
 — wheels, 59.
 — rollers, patent, 60.
 — conical, 61.
 Fuel, quantity and efficiency of, 141.
 Fulling, in the woollen manufacture, 1021.
 — mill for cloths, 501.
 Furnace, blast, in iron works, 562.
 — refining and puddling, 570, 571.
 — residuum of, in iron works, 567.
 — for pipe-makers, 674.
 — in glass works, 691.
 — for enamelling, 714.
 Fusee of clocks, 883.
 Garden engine, description of, 366.
 Gas from oil, 836.
 Gas-meter described, 831.
 Gasometer, 823.
 Gas works, history of, 802.
 — first attempted, 810.
 — present process described, 822.
 Gauge cock for steam boilers, 188.
 — steam, 190.
 — barometer, for steam-engines, 200.
 Gensanne's form of steam-engine, 157.
 German snail for raising water, 340.
 Gig-mill in cloth manufacture, 1022.
 Gilding pottery and porcelain, 669.
 — buttons, 865.
 — general methods of, 935.
 Gin for raising weights, 399.

Index.

Manufactures.

Gland for engaging and disengaging machinery, 50.
 Glass works, history of, 675.
 — materials for making, 680.
 — for optical purposes, 681, 684, 699.
 — grinding and polishing, 703.
 — for refracting telescopes, 1106.
 — polishing, 704.
 — gull, 690.
 — furnace, 691.
 — cutting process described, 696.
 — works, at Ravenhead, 679.
 — method of colouring, 710.
 — and other buttons, 868.
 Glasses for watches, 693.
 Glazing, in calendering, 392.
 — in the potteries, 663.
 Glue, manufacture of, 1141.
 Gold-beating, 931.
 — wire, drawing, 933.
 Governor for regulating motion, 66, 70.
 Grant's biscuit-making machine, 1115.
 Granulating machine for gunpowder, 722.
 Gridiron pendulum, 890.
 Grinding in cutlery and hardware, 917.

 — to solid iron shafts, 53.
 — hollow iron shafts, 54.
 — strength of, 55.
 — table of, for water wheels, 56.
 Gun founding, 926.
 — making, 937.
 — flints, manufacture of, 947.
 Gunpowder, manufacture of, 717.
 — different qualities, &c., 723.
 Gurney's locomotive carriage for common roads, 318.
 Hackling, in hemp manufacture, 1002.
 Hague's coining apparatus, 878.
 — method of working by means of a vacuum, 208.
 Hair-rope machine for raising water, 340.
 Hammer mills, 522.
 — riveting, block machinery, 378.
 Hand mill, 81.
 Hardware and cutlery, 914.
 Hat manufacture, 1059.
 Hemp and flax manufacture, 997.
 Hero's application of steam to produce motion, 145.
 High-pressure engine by Leupold, 155.
 — modern, 205.
 Hops, the revenue derived from, 1124.
 Horizontal windmill, 108.
 Hornblower's patent for steam-engine, 170.
 Horn press, 428.
 — buttons, manufacture of, 862.
 Horse and cattle mill, 93.
 — power, 2.
 — actual and nominal, 3.
 Hosiers, history of, 1046.
 Howard's vapour engine, 207.
 Hull's patent for steam boats, 156.
 Hydraulic engine, history of, 340.
 — ram for raising water, 342.
 — main in gas works, 826.
 — oil press, 510.
 Hydrostatic jack for lifting weights, 400.
 — packing press, 423.
 Jacks for raising weights, hydrostatic, hand, &c., 400.
 — for roasting, 408.
 — smoke, 409.
 Jenny spinning, cotton manufacture, 992.
 Jigger used in the potteries, 654.
 Inclined planes on railways, 299, 306.
 Indicator for steam-engines, 444.
 Indigo works, description of, 601.
 — culture of, 603.
 — mill, 484.
 Laking table, 1083.
 Iron mines, history of, 229.
 — railways, 292.
 — piling for wharfs, 309.

Index.

Iron works, description of, 605.
 — wharfs, construction of, 860.
 — wheels, construction of, 38.
 Kneading rollers in biscuit-making, 1115.
 Lace and bobbin-net manufacture, 1041.

 — Ure's experiments, 130.
 Lathe, original form, modern foot described, 412.
 — for facing ship blocks, 380.
 — for turning pins ditto, 381.
 Lead, manufacture of, 588.
 — mines, British, production of, 215.
 — pipes, casting and drawing, 927.
 — pencils, their manufacture, 1139.
 Leather, tanning, tawing, &c., 793.
 Lenses, proper curves for telescopes, 1105.
 Leupold's high-pressure steam-engine, 155.
 Leys, preparation of, in bleaching, 748.
 Lifting jack, jack in the box, &c., 400.
 Lighthouses, account of the English, 837.
 — revenue of, 839.
 — experiments on the most effective modes of lighting, 841.
 Lighting manufactories, 845.
 Lithographic printing, 1096.
 Liverpool and Manchester railway, 303.
 — experiments on, 305—308.
 — opening of, and accident to Mr. Huskisson, 309.
 — performance on, 311.
 Locks, various, description of, 414.
 — of guns, 945.
 Locomotive engines, first employment of, on railways and on roads, 293.
 — resistance of, on railways, 299.
 — description of, 312.
 — application to common roads, 314—316.
 — Parliamentary report on, 315.
 Logwood mill and preparation of, 485.
 Looking-glasses, silvering of, 450.
 Loom, common one described, 1032.
 — stocking weaving, 1047.
 — for fishing-nets, 1050.
 Machine, definition of, 1.
 — for planing wood, 416, 4
 — iron, 419.
 — for weighing, 457.
 — for proving iron cables, &c., 433.
 — for punching iron, &c., 438.
 — for ornamental punching, 441.
 — for registering, 443.
 — for silvering looking-glasses, 450.
 — for sowing, threshing, 452.
 — for drawing brass tubes, 455.
 — for reed-making, 457.
 — for biscuit-baking, 1115.
 — for dressing flour, 498.
 — drawing, in the Royal Mint, 877.
 — for forming ship blocks, 370.
 — for boring ship blocks, 372.
 — for mortising blocks, 373.
 — for shaping blocks, 374.
 — for scoring blocks, 375.
 Machinery, methods of engaging and disengaging, 50.
 Machines, miscellaneous, 370.
 — friction of, 23.
 — simple and compound, 319.
 — blowing, various kinds of, 385.
 — for boring cylinders, 386.
 — wooden pipes, 387.
 — stone pipes, 388.
 — for copying writing, 401.
 — for making cards, 402.
 — for counting, various kinds of, 403.
 Malt, revenue of, 1123.
 Malting, history of the malt duty, 1123.

Manufac-
tures.

Malting, theory of, 1117.
 Man hole in steam boilers, 191.
 Mangle, common, Baker's, &c., 389.
 Manufacture of iron described, 553.
 ——— comparison of materials employed, with the product, 559.
 Mashing-tun for porter brewers, 1128.
 Maudslay's vibrating steam-engine, 287.
 ——— engine for cutting the teeth of wheels, 337.
 Maximum effect of labour, 5.
 ——— overshot wheels, 114.
 Men, action and power of, at a windlass, 74.
 Mill-work, definition of, &c., 26.
 ——— framing of, 62.
 ——— for bolting flour, 497.
 ——— for bruising malt, grain, &c., 500.
 ——— for fulling cloths and flannels, 501.
 ——— for cutting out blanks in coining in the Mint, 877.
 ——— sizing and stamping, 877.
 ——— for flattening gold wire, 934.
 ——— blending, in pottery, 651.
 ——— for sugar-canes, 727, 728.
 ——— steel, for mines, 240.
 ——— stones, method of making, bedding, &c., 492.
 Mills, form and construction of, 80.
 ——— simple hand, 82.
 ——— tread, 83.
 ——— horse and cattle, 93.
 ——— wind, 94.
 ——— post, 95.
 ——— tower or smock, 96.
 ——— water, 110.
 ——— horizontal wind, 108.
 ——— and mill-work, authors on, 122.
 ——— of various description, 458.
 ——— bark, by Weldon, Chapman, &c., 459—461.
 ——— cement, for grinding. His Majesty's Dock-yard, Sheerness, 465.
 ——— for mixing mortar, pug-mill, &c., 466.
 ——— for grinding colours, indigo, &c., 483.
 ——— for cutting logwood, 485.
 ——— corn, flour, description of, 491.
 ——— for expressing oil, 504.
 ——— cocoa-nut oil, 512.
 ——— for rolling and forging, 514.
 ——— for working forge hammers, 522.
 ——— for sawing wood, 523.
 ——— marble, 538.
 ——— for the manufacture of snuff and tobacco, 545.
 Mines, copper, tin, lead, 211—215.
 ——— iron and coal, 223—230.
 ——— steam power employed in, 216.
 Mining processes in working for copper and tin, 223—225.
 Mixing machine in biscuit-baking, 1115.
 Mint, Royal, description of, 876.
 Modelling and casting busts, statues, &c., 1100.
 Mordants used in dyeing, 759.
 Morland's steam-engine, 148.
 Mortars, composition of, 475.
 Motion, regulators of, 63.
 ——— conversion and transmission of, 71.
 Motive and retarding forces, effect of on machines, 25.
 Movers, first, definition of, 2.
 ——— advantages and disadvantages, 12.
 ——— men, 4.
 ——— horses, 3.
 Mule spinning, 982, 996.
 Nail-making, 948.
 Needle-making, 954.
 ——— grinding, 957.
 Newcomen's original steam-engine, 154.
 New river, account of its formation, 854.
 ——— estimate of its work, 855.
 Oil, quantities imported and exported, 513.
 Oil-gas apparatus, 836.
 Oil-mill, common, and hydraulic oil press, 504, 510.
 Overshot water wheel, velocity of, 113.
 ——— maximum load of, 114.
 Paddle-wheels, action of, 274—281.
 Paper-making by hand, 1066.

Paper-making by machines, 1067.
 Paper-staining, 1147.
 Papin, claim to the invention of the steam-engine, 149, 152.
 Parallel motion for steam-engines, 201.
 Parkinson and Frodsham's pendulum, 889.
 Parliamentary investigation relative to steam navigation, 250.
 ——— report, 269.
 ——— on the application of locomotives to common roads, 315.
 ——— inquiry on the waterworks of the metropolis, 858.
 Paternoster work for raising water, 347.
 Payne's first scientific inquiry relative to the power of steam, 158.
 Pendulum for regulating motion, 64.
 ——— applied to clocks, 883.
 Pendulums of various kinds, 883—895.
 Penstocks for water-wheels, 119.
 Perrier's distilling apparatus, 1131.
 Phillips's power capstan, 393.
 Pile-engine, description of, 367.
 ——— proper height of, 368.
 Pin-making, 958.
 Pin-turning and polishing machine, 381.
 Pipes and cylinders in steam-engines, 192.
 Pipe-making furnace, 671.
 Piston, hemp-packed, 198.
 ——— metallic expanding, 199.
 Pix of the Mint, note, p. 610.
 Planing machine by Bentham, 416.
 ——— Bramah, 417.
 Plate glass, manufacture of, 685, 702.
 Plated manufacture, 959.
 ——— buttons and white metal buttons, 866.
 Platina, method of working, 593.
 Plumber blocks and steps, 58.
 Plunger pumps, 345.
 Polishing marble, how effected, 539.
 Pontifex's steam-engine, 163.
 Porter brewery, 1125.
 Post mill, 95.
 Potash, mode of obtaining, 610.
 Potter's contrivance for self-acting cock for steam-engine, 157.
 Pottery, different description of, 642.
 ——— processes and manipulation, 645.
 ——— handling, figuring, pressing, &c., 656.
 Power of steam-engines, 209.
 ——— aggregate, of steam-engines, 222.
 Power loom, invention of, 984.
 ——— description of, 1036.
 Press house in gunpowder works, 721.
 Presses, different kinds of, 421.
 ——— with differential screw, 422.
 ——— hydraulic, for packing, 423.
 ——— power gained, and strength required, 426.
 ——— for shaping horn, tortoiseshell, &c., 428.
 ——— for bookbinders and stationers, 429, 431.
 ——— for joiners, founders, &c., 432.
 Pressure engine for raising water, 341, 349.
 Printing, the history of, 1074.
 ——— press, common, 1078.
 ——— Stanhope's, 1079.
 ——— Ruthven's, 1080.
 ——— calicoes, &c., 774.
 ——— by resists, 779.
 ——— by discharges, 780.
 Propelling and resisting forces in steam vessels, 273.
 Proving machine, Royal Dock-yard, Woolwich, 433.
 ——— the strength of gunpowder, 435.
 ——— balls and shells, 436.
 Puddling furnace in iron works, 571.
 Pump, simple forcing and sucking, described, 346.
 ——— sucking, by Taylor, 351.
 ——— forcing, by Stephens, 352.
 ——— double piston, by Hedderwick, 353.
 ——— by Franklin, 354.
 Pumping and draining mines, 226.
 Pumps of various description, 344.
 ——— worked by cranks, 348.
 ——— centrifugal, described, 350.
 ——— for ships, by Smeaton, Noble, Kingston, Jekyl, 355—360.
 ——— chain, for ships, 361.
 ——— employed in mining, described, 227.
 Punching machine, 438.

 Ventilating manufactories, 847.
 Ventilation of coal mines, 236.
 Viameter for measuring distances, 404.
 Vibrating steam-engine, 206.
 — cylinder applied to a steam vessel, 286.
 Vinegar, manufacture of, 631.
 — works, 631.
 Vitriol works, description of, 627—630.
 Under-shot water wheels, construction of, 115.

Under-shot water wheels, effect of, 116.
 Universal joint for coupling, 48.
 Ure's experiments on latent heat, 130.
 — apparatus for ascertaining the elastic power of steam, 133.

Index.

Warming manufactories, 845—848.
 Warping mill, 1031.
 Watch glasses, method of forming, 698.
 — dial enamelling, 713—716.
 Watches, construction of, 902.
 Water, as a first mover, 8.
 — wheel, buckets of, 111.
 — over-shot, velocity of, 113.
 — under-shot, construction of, 115.
 — quantity raised by the Cornwall steam-engines, 220.
 — works, history of, 852.
 — proposed improvement in, 857.
 — proof cloth, manufacture of, 1156.
 — cements, composition of, 479.
 Watt's remarks on the latent heat of steam, 125.
 — improvement in steam-engine, 164, *et seq.*
 — double-acting engine, 174.
 Weaving, 1030.
 Weaving, different kinds of, 1030—1034.
 Weighing machines, 457.
 Whale oil, processes employed in obtaining, 632.
 Wharfs, construction of, 860.
 — Patent cement, 861.
 Wheel carriage counting machine, or viameter, 404.
 Wheels, balance, over-shot, under-shot, breast, 8.
 — comparative power of, 9.
 — teeth of, 27.
 — strength of, 34.
 — bevelled teeth of, 33.
 — cogged, construction of, 37.
 — iron, construction of, 38.
 — hanging of, 39.
 — strength of, 41.
 — friction, 59.
 White lead, mode of manufacture, 608.
 Wind, as a first mover, 7.
 — mills, construction of, 94.
 — sails of, &c., 99, *et seq.*
 Windlass, description of, 395.
 — action of men at, 74.
 Wiredrawing, gold, 933.
 — common method, 966.
 — quantity used in a day at Dyer's card-making manufactory, 402.
 Wooden pendulums, 896.
 — railways, 291.
 Wool mill, or devil, 1017.
 — combing by hand, 1027.
 — by machinery, 1028.
 Woollen and worsted manufactures, history of, 1014.
 Wootz, or Indian steel, 581.
 Worcester, Marquis of, project of a steam-engine, 146.
 Worsted manufacture, 1026.
 Woulfe's steam-engine, 177.
 Wright's Patent distilling apparatus, 1131.
 Zinc, manufacture of, 592.
